INTRODUCTION

Most of the studies hitherto published on the pathogenesis of urinary tract infection in childhood are concentrated on anatomical abnormalities, mainly congenital and acquired obstructions, and on the question of nephropathogenicity of certain bacteria. Although immunologic mechanisms are known to play an important role in the defence against infectious diseases and can influence their course surprisingly scarce information has until recently been available on the immune response of patients with urinary tract infections. Further this information is to some extent controversial. This may at least in part, depend upon the heterogeneity of the materials investigated comprising obstructed and nonobstructed, first-time and recurrent infections in both sexes and in patients of very different ages.

For this reason we found it necessary to study the antibody response in a strictly defined material of children with first-time urinary tract infections. As the passive haemagglutination method, commonly used for determining the antibodies in the patients sera, is dependent upon the use of antigens derived from the infecting bacterial strains, it is too complicated for clinical routine and it was thus judged important to search for alternative antigen sources.

It is the aim of the present investigation to answer the following questions

1. What is the normal course of the antibody response measured by means of the passive haemagglutination method, during an acute urinary tract infection
   a) with signs of renal involvement
   b) without signs of renal involvement
   c) with regard to the age of the patient
2. Which alternative antigen sources may be employed as substitutes for the infecting urinary bacteria.

Further it will be shown that determination of the antibody titres may be used to

a) differentiate pyelonephritis from lower urinary tract infection in doubtful cases,

b) diagnose pyelonephritis in suspected cases with inconclusive urinary findings,

c) demonstrate the etiology in obscure cases, where chronic pyelonephritis may be a possibility

d) illustrate some immunologic relationships between mother and newborn.

METHODOLOGIC STUDIES

The method used for determination of antibodies to *E coli* throughout this investigation was the technique of passive haemagglutination. This method is based on the principle that certain bacterial antigens are adsorbed to red blood cells and thereby become agglutinable by the antibacterial antibodies. It was first described by Keogh North and Warburton in 1947 (11) for the determination of agglutinins to the *Haemophilus* group It has later been adopted by several investigators for use in different infections, for instance tuberculosis by Middlebrook and Dubos (21) and Lagercrantz (16) streptococcal infections by Kirby (12) and for *E coli* originally by Hayes (9)

A thorough investigation of the influence of variations of the passive haemagglutination technique on its specificity was published by Madsen in 1954 (20) He found that sheep erythrocytes were most suitable for the haemagglutination reaction as they gave stable suspensions and distinct agglutination patterns with clear-cut titre limits After sensitization the cells could be stored for several days at 4–6 C. He found that the haemagglutination reaction was highly specific since the red cells sensitized with extracts of *E coli* were agglutinated only by the homologous 0-group antiserum This however is not quite true as some crossreactions exist between certain 0-groups This was shown by Kunin and Beard (16) who in 1963 presented a survey of the relation between most of the known *E coli* 0-antigens and their corresponding antisera. They were able to demonstrate a limited number of cross reactions between some 0-antigens.

The high specificity of the passive haemagglutination reaction was verified in the present study It has been observed repeatedly that antigens, prepared from *E coli* belonging to another 0-group than the one found in the actual patient's urine gave haemagglutination titres only within the normal limits whereas with the antigen from the infecting bacterial strain elevated titres were found Similar results were obtained when sera were tested with antigens derived from the same bacterial strains isolated from the urine at different episodes of urinary tract infections. Further haemagglutination inhibition experiments have clearly demonstrated that the haemagglutination reaction of red blood cells sensitized with a certain antigen will always be completely inhibited by preincubation of the serum with the same antigen but not with an antigen of a different 0-type It is thus of vital importance for the reliability of the method that the antigen employed is derived from the same *E coli* 0-group as the one infecting the patient or at least has a close antigenic relationship to this type In this study therefore the patients sera were generally tested with antigen derived from their own urinary bacteria

Storing of sera

Early during this study it was noticed that high titres found in the sera within a few days after the sample collection could not be reproduced when the sera

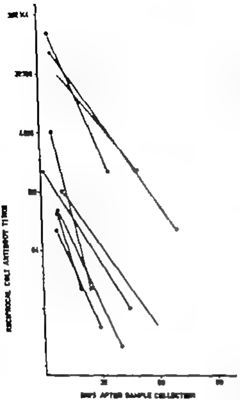

Fig. 1. Nine serum samples titrated with their corresponding antigens shortly after the sample collection and again one to two months later. The sera were in the mean-time stored at +4 °C.

Table I. Monthly titrations of 7 sera stored at temperature of −20 °C. The results are expressed as titration steps.

Serum	Months after sample collection						
	0	1	2	3	4	5	6
1	13	13	15	13	14	13	[illegible]
2	12	10	13	13	11	12	12
3	17	17	18	17	17	17	18
4	10	17	16	18	[illegible]	16	—
5	15	16	16	15	16	16	17
6	12	13	12	13	12	11	12
7	16	15	15	16	17	16	—

were titrated again after about one month (Fig. 1). The sera were in that stage of the investigation kept in a refrigerator at +4 °C. To test the importance of the temperature some sera were kept at −20 °C and titrated once a month for five or six months. The results are presented in Table I, which shows that for the period of time studied the sera preserved their antibody activity. Since then all sera were stored at −20 °C till used.

Antigen studies

A. Antigen preparation and concentration. For sensitization of the sheep erythrocytes the supernatant of a centrifuged boiled suspension of the actual bacteria was used as described by Neter *et al.* (22) and presented in detail in I.

In most of the experiments the concentration of the antigen was standardized by comparison of the unboiled bacterial suspension to a McFarland scale and adjusting the concentration to about 1200 million bacteria per ml. In the experiments with polyvalent antigen (VI) equal parts of eight antigen suspensions of different O-types of this strength were mixed and the concentration of each antigen was thus reduced to about 150 million per ml. To ascertain that this concentration was sufficient to obtain the same titres, a series of titrations of sera with erythrocytes, sensitized with different dilutions of the homologous antigens, were performed. The results are presented in Table II from which it appears that dilutions to 1:20 (equal to [illegible] million bacteria per ml) still gave the same results as undiluted antigen suspensions. Thus each separate antigen was still present in excess when used in the polyvalent antigen. The results

Table II Titrations of 5 sera with sheep erythrocytes sensitized with homologous antigens in different dilutions. Undiluted antigens are derived from a stock containing about 1200 million bacteria per ml. The results are expressed as titration steps.

Serum	Antigen dilutions 1:1	1:5	1:10	1:20	1:30	1:40	1:50	1:100
1	9	10	10	9	6	4	3	1

3	15	14	15	15	10	8	4	1
4	15	15	16	15	9	9	5	1
5	13	13	1	13	8	7	6	1

obtained by means of the polyvalent *antigen can therefore be regarded as* comparable to those found with the individual antigens.

B Sources of antigen The main part of the methodologic studies during this investigation was devoted to the possibility of using antigen sources other than the infecting urinary strains This was of interest mainly for two reasons. *Firstly* because it was found necessary to find an adequate substitute for the urinary bacteria in cases suspected of urinary tract infections, but with negative urinary cultures Secondly it was deemed of practical value if it were possible to exclude the time-consuming and vulnerable process of preparing antigens from the strain isolated from each patient s urine for the study of the antibody response

1 F a e c a l c o l i a n t i g e n s (III) The background for these experiments were the findings of Turck *et al* (20) and Vosti *et al.* (32) that the serologic type of *E coli* found in the urine from patients with urinary tract infections was usually also present in their faeces and, in most cases identical with the *predominant* strain there To verify this, the antibody titres of a series of pyelonephritic patients were determined simultaneously with antigens derived from strains isolated from urine and faeces from each patient The results were compared to the results of serological typings of the strains from *both sources It was found that the faecal* bacteria might be used for antigen preparation with some success but the frequency of positive findings were lower than when the urinary strains were employed This was due to the fact that the frequency of identical serotypes in urine and faeces was considerably lower in our *patients than the frequency found by the* previously mentioned authors. This may at least partly depend upon differences in technique as described in detail in III

2 C o m m o n e n t e r o b a c t e r i a l a n t i g e n (V) In consequence of the partly unsatisfactory results of the use of the patients faecal bacteria the interest was focused on the common enterobacterial antigen, accidentally discovered by Kunin *et al* in their studies of cross reactions between different *E coli* O-antigens and their antisera (16) During this study they found that antisera to O14 O50 O124 and O144 gave haemagglutination reactions with almost all *E coli* O-antigens and with antigens prepared from other *Enterobacteriaceae* as well

A crude preparation of the common enterobacterial antigen, prepared from *E coli* O14 which contains the greatest amount of this antigen (15) was used for sensitization of sheep erythrocytes and a series of patients were tested longitudinally with this antigen simultaneously with antigens derived from the infecting bac-

teria from these patients. The results showed clearly that the common antigen could not substitute the homologous antigens. Almost all patients sera were found to have low titres against the common antigen, but only two out of 22 had variations in this titre and these variations were very slight. Further it appeared from this investigation, that antibodies to the common enterobacterial antigen did not interfere with the determinations of antibodies to the homologous urinary or faecal bacterial strains. This conclusion was based on haemagglutination-inhibition experiments, showing very slight or absent reduction of the antibody titres determined by means of the O-antigens of the infecting strains in sera, preincubated with the aforementioned preparation of the common antigen.

3 Polyvalent E. coli antigen (VI). Experiments with antigens other than the homologous urinary strains, were also performed with erythrocytes simultaneously sensitized with eight different *E coli* O-antigens. The experiments were based on the findings of several authors (7 25 27 29 32) who showed that relatively few O-groups of *E coli* are responsible for most of the urinary tract infections observed in the patients. Thus, it appeared possible to detect the antibodies in most patients if the carrier cells could be sensitized with a sufficient number of different *E coli* O-antigens.

To investigate this, a series of experiments were performed with rabbit *E coli* antisera, titrated with erythrocytes coated with varying numbers and combinations of different *E coli* O-antigens. It was found that not only could at least eight antigens be simultaneously adsorbed to the red blood cells, but the reactions obtained were of the same magnitude and of the same specificity as when the antigens were used individually

The specificity of the reaction with the polyvalent antigen were confirmed in a series of clinical experiments. The titres against the polyvalent antigen was found to run a course parallel to the titres of the homologous antigen in those cases where the homologous antigen belonged to one of the O-groups, included in the polyvalent antigen.

This modification of the method for determining antibodies to *E coli* seems to offer a reliable alternative to the original method and to make it easier to utilize antibody determinations in clinical routine. At the same time it is a readily available and adequate instrument for use in sera from patients who for various reasons have negative urinary cultures.

Accuracy of titration results All titrations of sera from patients and controls were performed in twofold serial dilutions of the sera and were made in duplicate A good correlation was found between these double determinations (Fig 1 in II)

Because of the extremely high titres found in several sera it was regarded necessary to check the precision of the serial dilutions. For this purpose a twofold serial dilution of serum containing an amount of J[131] was prepared, using one pipette for each serum as in the routine titrations and the dilutions of the isotope were determined in a Geiger-counter In this way it was found that, within a confidence limit of 95 per cent, the dilution factor was between 0.5 and 0 6 with a mean value of 0.55 (9a)

This error means that the titres will be

read slightly higher than the true titres are With a dilution factor of 0.55 instead of the intended 0.5 a true titre of 128 will be read one step too high (i e. 256) and a true titre of 32 768 two steps too high. However the tests performed show that the error is very constant and thus of minor importance.

ANTIBODY TITRES TO E COLI IN UNINFECTED CHILDREN

A survey of the literature published before these studies were begun gave only scanty information concerning the presence of *E coli* antibodies in uninfected children. Using passive haemagglutination, Neter *et al* (24) determined the antibody titres against the enteropathogenic strains 026 055 and 0126 in 323 sera mainly from infants and children and found that the titres increased with the age. Of more interest to this study is the publication by Kunin (14) where he tested sera mainly from children against six of the 0-groups commonly encountered in urinary tract infections (01 02 04 06 07 and 075) Even in this study increasing titres with age could be demonstrated.

In the present study the antibody titres were determined in three series of children (II, V VI) without infections, past or present, in the urinary tracts The children investigated for this purpose were carefully selected according to the following criteria.

1 No history of previous urinary tract infections or repeated unexplained febrile episodes.
2 Normal temperature and sedimentation rate at the time of the sample collection.
3 Less than 1000 microorganisms per ml of urine at the time of the sample collection.

The results of the titrations in these controls were presented in II V and VI In II sera from 80 children were tested with *E coli* antigens prepared from the childrens own faecal flora This was regarded as the most adequate antigen source for comparison with the titres in the patients, where the antigen source was their urinary bacterial flora as it is generally assumed (29 32 34) that the coli bacteria invading the urinary tract originate from the intestinal flora.

In V the 36 controls were tested with their own faecal bacterial antigens as well as with a crude preparation of Kunin s common enterobacterial antigen derived from a strain of 014

Thus a total of 116 sera from healthy controls were tested with antigens derived from their own faecal *E coli* flora and it was found that almost all children above the age of two months possessed antibodies against these antigens. The maximum titre found in any of the controls was 128 which was found in one child. All other sera had titres of 64 or less. In the eleven infants below two months of age in these two groups no antibodies were found in eight, while three had titres of 2 16 and 64 respectively

The antibody titres to the common enterobacterial antigen were lower than

or—in four cases—equal to the titres determined with the antigens from their faecal coli strains.

In study VI, 133 controls were tested with erythrocytes, simultaneously sensitized with eight of the O-antigens, most commonly encountered in urinary tract infections. The titres against this polyvalent antigen showed the same general trend as the titres found with the antigens from the patients faecal coli strains i.e. very low in early life and increasing throughout the age period studied. It is somewhat surprising to find that the titres found by means of the polyvalent antigen are generally higher than in the controls tested with their faecal bacterial antigens. It is less probable that the titres obtained with several antigen bound to the same erythrocytes will be the sum of the titres against each of the antigens. It would rather be expected that the titre determined with the polyvalent antigen would be identical with the highest titre to anyone of the individual antigens. This would be in agreement with observations in patients with urinary tract infections in theses studies (Fig 4 in IV) As the bacterial antigens included in the poly valent antigen represent the most commonly encountered bacterial strains not only in the urinary tract, but also in the faecal flora (29 32) it is possible that most of the control cases have for long periods of time harboured one or more of these bacterial types in their intestinal tracts and have therefore been exposed to a long-standing stimulation to antibody production against these

ANTIBODY TITRES IN PATIENTS WITH ACUTE, UNCOMPLICATED URINARY TRACT INFECTIONS

One of the problems met with in the diagnosis and clinical management of urinary tract infections is the difficulty of judging whether an infection involves the kidney or not. It is generally accepted that febrile urinary tract infections are usually combined with renal infection, but the frequent absence of fever or any general symptoms at all, in patients with chronic pyelonephritis makes it obvious that diagnosis of cystitis cannot be justified before renal involvement has been excluded by means of laboratory methods It was therefore judged of interest to see whether a difference existed between the antibody responses in urinary tract infections with and without renal involvement To investigate this, the antibody titres were determined in a series of patients with acute uncomplicated urinary tract infections (I II)

The diagnosis was based on the clinical symptoms and urinary findings of leucocytes and bacteria in significant amounts. The disease was defined as pyelonephritis in patients with fever elevated sedimentation rate and impairment of the renal concentrating capacity during the acute phase, and as cystitis only if all of the three above-mentioned signs were absent.

The studies showed that the patients above three months of age with pyelonephritis almost invariably had a marked increase in the antibody titre against the

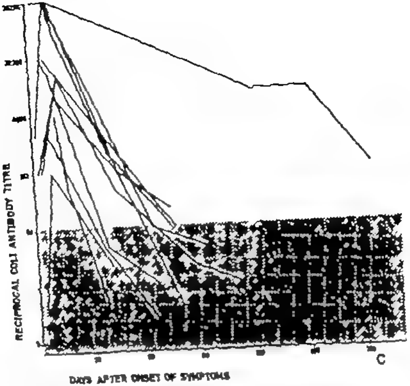

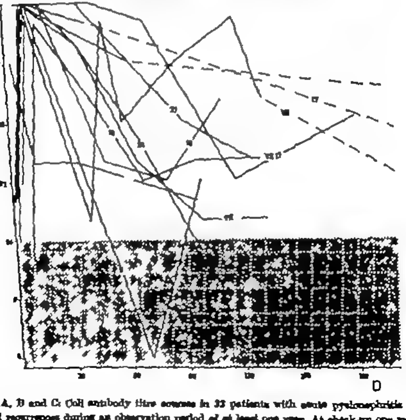

Fig. 2. A, B and C: Coli antibody titre courses in 33 patients with acute pyelonephritis without signs of recurrences during an observation period of at least one year. At check-up one year after the onset of symptoms the titres were normal in all cases except one.

Fig. 3 D: Titre courses in 11 patients with acute pyelonephritis and

infecting strain. In the patients with cystitis, on the other hand the titres remained within the range found in the controls Thus it appears that the determination of the antibody response in patients with urinary tract infections is a useful tool in differentiating between patients with pyelonephritis and with cystitis.

This unfortunately does not hold true in infants below the age of two months. During this investigation antibody titres were determined in sera from 30 infants of this age group (1) Although most of these patients in addition to their urinary findings had signs of serious infections such as extreme weight loss (more than 10 per cent of the body weight) vomiting and in several cases, severe septic infection with positive blood culture the titres obtained were generally very low One patient, aged 50 days had a titre of 4000 while in the rest of the cases the maximal titre found was 64. In only seven other infants significant rises of threefold increase in titre could be observed in consecutive samples

The reason for this is not clear It is generally agreed upon that newborn babies are able to produce antibodies of this type In a recent paper Florman and Lambertson (6) demonstrated production of antibodies to E coli 04 in three premature infants infected with this type Lodinova et al (19) found significant titre rises in the serum of newborn infants to E coli 083 after artificial colonization of the intestinal tract. On the other hand, when they determined the antibody titres against antigen from the spontaneously occuring bacterial flora of the faeces they found very low titres

One explanation for the lacking antibody response to E coli infection observed in the infants may be that the infections are caused by bacteria colonizing the mother and against which she has produced antibodies. IgG antibodies are known to be able to pass from the mother to the foetus via the placenta. Their presence in the infant s blood at the time of the infection may inhibit the production of IgM antibodies (8)

In several bacterial or viral infections serologic reactions show a certain relationship to the course of the disease and are thus helpful in the evaluation of the outcome of different therapeutic measures and of the disease itself

It was therefore found of interest to investigate the relation between the clinical course of the disease and the pattern of the antibody response

For this purpose the 58 patients with pyelonephritis included in studies II and V were selected Thirty three of these patients followed for at least one year (in most cases more than three years) did not during this observation period show any signs of recurrence symptomatic or asymptomatic. The antibody titres determined during their illness and convalescence are given in Figs. 3 A, B and C It appears from these that the titres had their maximum between 5 and 15 days after the onset of the symptoms and that they with a few exceptions fell to normal values within 90 days Three patients in this group show a definitely delayed decrease in the antibody titres. They are still being followed, but have not shown any traditional signs of recurrence or chronic disease One of these patients still have an elevated titre more than three years after the infection. The other 32 patients

Table III Findings in 11 patients with their first recurrence after an acute pyelonephritis. The courses of the antibody titres are illustrated in Fig. 2 D

Patient no.	Time after initial infection	F brile (+) or afebrile (−) recurrence	Serotype at initial infection	Serotype at recurrence
6	3 months	+	06: :H4	02: :H2
14	8 months	+	01 :H–[a]	Klebsiella
15	3 months	−	06: :H4	075: :H
16	3½ months	+	02: :H4	Strept. faecalis
17	11 months	+	01 :H–	ND[b]
18	4 months	−	06: :H4	06: :H4
24	36 months	+	04: :H?[c]	ND
27	3 months	+	085: :H11	Enterococci
VII 4	2 months	+	06: :H7	06: :H4
VII 8	3 months	−	06: :H4	06: :H4
VII 17	6 months	+	075: :H10	rough: :H17

[a] 01 :H– means *E. coli* O-antigen 1 and immotile, no H-antigen. The empty space between the two colons is for the K-antigen. The K-antigens were not examined in this study

[b] ND = not done.

[c] H? means motile, but not agglutinated with the established 49 H test sera.

in this group had normal titres at a check-up one year after the infection.

Agglutination methods favour the demonstration of IgM antibodies (8). Although IgG antibodies against the coli O-antigens can also be shown, IgM antibodies are generally assumed to dominate the antibody response to this antigen (8). The half life of IgM antibodies is about 5 days (3) and it is suggestive that the decrease in the antibody titres in the patients treated for acute pyelonephritis goes well with such a catabolic rate. Since IgM antibodies are assumed to be formed only in the presence of antigen (30) the rapid decrease of antibody titres in most of the patients in Figs. 2 A, B and C might indicate that the bacterial antigens are effectively eliminated by the treatment.

Out of the 58 pyelonephritic patients in studies II and V 11 have had recurrences during the observation period. Some relevant findings in these patients' recurrences are presented in Table III and the titres obtained are illustrated in Fig. 2 D. A comparison between the courses of the antibody titres in the patients with and without recurrences shows two noteworthy findings. First, it is obvious

infecting strain. In the patients with cystitis on the other hand the titres remained within the range found in the controls. Thus it appears that the determination of the antibody response in patients with urinary tract infections is a useful tool in differentiating between patients with pyelonephritis and with cystitis.

This unfortunately does not hold true in infants below the age of two months. During this investigation antibody titres were determined in sera from 36 infants of this age group (1) Although most of these patients in addition to their urinary findings had signs of serious infections such as extreme weight loss (more than 10 per cent of the body weight) vomiting and in several cases, severe septic infection with positive blood culture the titres obtained were generally very low One patient, aged 50 days had a titre of 4096 while in the rest of the cases the maximal titre found was 64 In only seven other infants significant rises of threefold increase in titre could be observed in consecutive samples.

The reason for this is not clear It is generally agreed upon that newborn babies are able to produce antibodies of this type In a recent paper Florman and Lambertson (6) demonstrated production of antibodies to *E coli* 04 in three premature infants, infected with this type Lodinova *et al* (19) found significant titre rises in the serum of newborn infants to *E coli* 083 after artificial colonization of the intestinal tract. On the other hand, when they determined the antibody titres against antigen from the spontaneously occuring bacterial flora of the faeces they found very low titres

One explanation for the lacking antibody response to *E coli* infection observed in the infants may be that the infections are caused by bacteria colonizing the mother and against which she has produced antibodies IgG antibodies are known to be able to pass from the mother to the foetus via the placenta. Their presence in the infant s blood at the time of the infection may inhibit the production of IgM antibodies (8)

In several bacterial or viral infections serologic reactions show a certain relationship to the course of the disease and are thus helpful in the evaluation of the outcome of different therapeutic measures and of the disease itself.

It was therefore found of interest to investigate the relation between the clinical course of the disease and the pattern of the antibody response

For this purpose the 58 patients with pyelonephritis included in studies II and V were selected. Thirty three of these patients followed for at least one year (in most cases more than three years) did not during this observation period show any signs of recurrence symptomatic or asymptomatic. The antibody titres determined during their illness and convalescence are given in Figs. 2 A, B and C It appears from these that the titres had their maximum between 5 and 15 days after the onset of the symptoms and that they with a few exceptions fell to normal values within 90 days Three patients in this group show a definitely delayed decrease in the antibody titres. They are still being followed but have not shown any traditional signs of recurrence or chronic disease One of these patients still have an elevated titre more than three years after the infection. The other 32 patients

inconclusive. It is of course difficult to be completely certain of the diagnosis of pyelonephritis even when this immunologic reaction is positive since a finding of an elevated antibody titre to a certain bacteria only demonstrates that the patient is infected with this strain, but not that this infection is localized to the kidneys. It is known that infections with *E coli* such as enteritis (23) and appendicitis (31) may elicit antibody responses to the infecting bacteria. However in view of the typical symptoms and findings, in particular the reduced concentration capacity in most of these patients it was regarded as most likely that they were suffering from pyelonephritis. A definite confirmation of the diagnosis might have been obtained by means of the technique employed by Aoki and McCabe (2) who used antiserum to the common enterobacterial antigen for immunofluorescent detection of bacterial antigen in renal biopsy specimens.

In study nr IV it was shortly discussed whether these infections differed from the traditional ones in other respects than the sparse urinary findings. It may therefore be of interest to present the findings at reexaminations three years after the original infections. Four of the patients (Cases nr 1 2 4 and 5) have in the meantime been completely free from symptoms from their urinary tracts and were found to be normal on examination including blood pressure readings, haemoglobin, ESR, urinary examination and culture and coli antibody determination. Case 3 had had occasional abdominal pains without fever or micturition symptoms. The antibody titre against the original faecal flora was again found to be elevated (1024) as well as against the polyvalent antigen (2048) All other findings were normal. Case 6 was treated abroad for a urinary tract infection two and a half years after the infection seen here, but at the reexamination she was free from symptoms or abnormal findings. Case nr 7 was again referred to this hospital two years after his first admission because of an elevated blood pressure found on routine examination. He had a blood pressure of 140–160/100–110 and was found to have heart enlargement and hypertensive retinopathy The true endogenous creatinine clearance was normal (170 l/24 h/1 73 m²), while the concentration capacity was slightly reduced (770 mOsm/l) Intravenous pyelography (IVP) showed progress in the parenchymal reduction earlier observed on both sides Repeated urinary cultures were negative. The coli antibody titres determined against polyvalent antigen as well as against antigens derived from the patient's faecal coli flora were normal. The possible presence of antibody titres against other *E coli* O-types than the eight included in the polyvalent antigen and those found in the patient's faeces was not investigated.

Case nr 8 has on two occasions been investigated because of micturition pains and on both occasions had leucocyturia but negative culture. Coli antibody titres were normal against the earlier employed urinary bacterial antigen and the polyvalent antigen.

Of these eight patients one has contracted serious renal damage consistent with the sequelae of pyelonephritis; another has had a recurrence, not observed here, and two have had minor symptoms,

that the antibody response is not less in the former group or in other words, the cause of the recurrences in these patients without macroscopic malformations in their urinary tracts could not be a deficient antibody response measured by the present method. It should be emphasized that this of course does not exclude the possibility of differences in other immunologic systems in these two patient groups Secondly it is of interest to observe that 4 of the patients in Fig 2 D and Table III (cases 6 14 16 27) had raised titres against antigens derived at the first infection although the reinfections were caused by a different serotype of *E coli* (case 6) or by different species (case 14 16 and 27) The reason for this phenomenon, which has been observed in other patients (cf. IV case 5) is not clear One possibility however is that it illustrates a latent infection which is reactivated by a reinfection, which may in itself be of minor importance

ANTIBODY TITRES IN PATIENTS WITH ATYPICAL ACUTE PYELONEPHRITIS

The term atypical pyelonephritis is in this survey used to signify cases with signs and symptoms typical for acute pyelonephritis, but lacking the usual urinary findings, i e without significant leucocyturia and bacteriuria That patients with chronic pyelonephritis for long periods of time may not excrete bacteria in the urine is well known (13) In acute cases this is less well recognized although several factors may cause low bacterial numbers in the urine such as presence of bacteriostatics pH below 5.5 very frequent micturitions or obstructions in the urinary tract It is also mentioned by Kass (10) that "abscesses may be produced in the kidney which do not discharge organisms into the tubules. Usually these are associated with manifest clinical evidence of sepsis and renal localization" The existence of such "closed" infections which do not communicate with the pelvis is further substantiated in a recent paper by Deliveliotis *et al* (5) who found abacteriuric renal infections in patients with solitary cysts of the kidneys

Abacteriuric experimental pyelonephritis in rats was recently reported by Schmidt *et al* (28) who injected *E coli* directly into the renal pelvis Urinary samples collected regularly for 8 weeks after the infection was established showed neither pyuria nor bacteriuria in 70 out of 209 samples Two of the 31 rats had completely negative urinary findings on all occasions The diagnosis was finally confirmed by histopathologic examination of the kidneys.

A series of patients of this type was investigated in IV The essential finding in this study was that the antibody titre courses in these patients were similar to those usually observed in pyelonephritic patients with pathologic urinary findings. This supports the diagnosis of pyelonephritis in cases, where the usual urinary findings are lacking or

inconclusive It is of course difficult to be completely certain of the diagnosis of pyelonephritis even when this immunologic reaction is positive, since a finding of an elevated antibody titre to a certain bacteria only demonstrates that the patient is infected with this strain, but not that this infection is localized to the kidneys. It is known that infections with *E coli* such as enteritis (23) and appendicitis (31) may elicit antibody responses to the infecting bacteria However in view of the typical symptoms and findings, in particular the reduced concentration capacity in most of these patients it was regarded as most likely that they were suffering from pyelonephritis A definite confirmation of the diagnosis might have been obtained by means of the technique employed by Aoki and McCabe (2), who used antiserum to the common enterobacterial antigen for immunofluorescent detection of bacterial antigen in renal biopsy specimens.

In study nr IV it was shortly discussed whether these infections differed from the traditional ones in other respects than the sparse urinary findings. It may therefore be of interest to present the findings at reexaminations three years after the original infections. Four of the patients (Cases nr 1 .., 4 and 6) have in the meantime been completely free from symptoms from their urinary tracts and were found to be normal on examination including blood pressure readings, haemoglobin, ESR, urinary examination and culture and coli antibody determination. Case 3 had had occasional abdominal pains without fever or micturition symptoms. The antibody titre against the original faecal flora was again found to be elevated (1024) as well as against the polyvalent antigen (2048) All other findings were normal. Case [illegible] was treated abroad for a urinary tract infection two and a half years after the infection seen here, but at the reexamination she was free from symptoms or abnormal findings. Case nr 7 was again referred to this hospital two years after his first admission because of an elevated blood pressure found on routine examination. He had a blood pressure of 140–180/100–110 and was found to have heart enlargement and hypertensive retinopathy The true endogenous creatinine clearance was normal (170 l/24 h/1 73 m²) while the concentration capacity was slightly reduced (770 mOsm/l) Intravenous pyelography (IVP) showed progress in the parenchymal reduction earlier observed on both sides Repeated urinary cultures were negative The coli antibody titres determined against polyvalent antigen as well as against antigens derived from the patient's faecal coli flora were normal. The possible presence of antibody titres against other *E coli* O-types than the eight included in the polyvalent antigen and those found in the patient's faeces was not investigated.

Case nr 8 has on two occasions been investigated because of micturition pains and on both occasions had leucocyturia but negative culture. Coli antibody titres were normal against the earlier employed urinary bacterial antigen and the polyvalent antigen.

Of these eight patients one has contracted serious renal damage consistent with the sequelae of pyelonephritis another has had a recurrence, not observed here, and two have had minor symptoms,

which are difficult to evaluate Nothing in the courses of these case histories differs from the course which might be anticipated in ordinary cases of pyelonephritis.

In these patients with history and symptoms suggestive of pyelonephritis, but with unconvincing urinary findings demonstration of antibodies in elevated titres strengthens the diagnosis. However as no urinary bacteria are available for antigen preparation in these patients it is necessary to obtain a related antigen from some other source This was originally the reason for investigating the patients faecal flora as an antigen source as described earlier

FURTHER CLINICAL USE OF COLI ANTIBODY DETERMINATIONS

Recurrent urinary tract infections

In several patients with urinary tract infection repeated recurrences are observed. In most cases a change of the bacterial flora is found from one infection to the next (4) Some patients of this type were followed for long periods and their symptoms and findings will be illustrated with the following case history

M M ♀ 54 07 16 This patient had her first known urinary tract infection in December 1959 and since then she has had several symptomatic and asymptomatic recurrences. From September 1962 she has been seen regularly at this hospital. September 1962 she was infected with a strain of *E coli* O21 :H19 causing a symptomatic infection and an elevated antibody titre to this strain (Fig 3) Six weeks later she was reinfected with an *E coli* O1:H– with fever and elevated ESR, but without local symptoms. The antibody titre was elevated against this new strain and remained high for a period of four months after which it decreased to only a slightly elevated level. During the period June 1963 to January 1964 the patient was not seen here but was, according to the parents and herself perfectly well. She reappeared for a check up in January 1964 and felt well was afebrile and had an ESR of 12 mm/1 h. In spite of that she was found to have leucocyturia and 1 million *E coli* O1 :H– Again, there was a high antibody titre against this strain. The titre persisted high for about three months and then dropped to a slightly elevated level. In July 1964 she had another asymptomatic infection, now with a strain of *E coli* O18. The titre against this strain remained normal. A new antibody titre rise against the O1-strain was found in November 1964 in connection with a new asymptomatic recurrence caused by O1:H– Since then no bacteria were found on numerous controls and the antibody titre has slowly returned to the normal level.

During the years of her illness, IVP was performed on three occasions. In April 1960 it was completely normal and in December 1962 a dilatation of the left pelvis and ureter was found. In March 1964 the left kidney showed some reduction of the parenchyma and coarse calyces. Urethro-cystography performed on the same occasions never showed any abnormalities, particularly no vesico-ureteral reflux.

In this patient where the findings have been normal for a three year period after a long series of recurrences, it seems likely that a definite healing of the infection has been obtained, although the progressive changes in the IVP may point to a healing with scarring of the left kidney

The following patient shows a constantly increased antibody titre in spite of only one recurrence after a urinary tract infection.

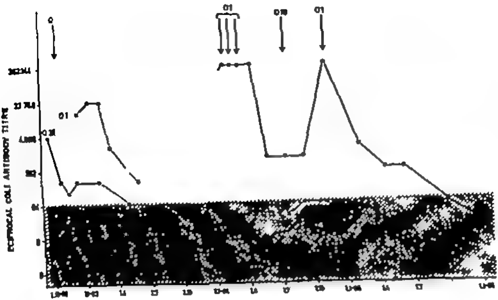

Fig. 3. Coli antibody titres in patient M. M. During the observation period the first infection was caused by *E. coli* O31:H19. The O-types at the recurrences are given in the figure.

E. W. ♀ 42 62 [illegible] This patient had her first known urinary tract infection in December 1960. Although she had no loin or abdominal pain and no micturition symptoms she had fever, heavy leucocyturia and significant bacteriuria. The renal concentrating capacity was reduced. After therapy with sulphonamide she was well with sterile urine. Only 23 days after the cessation of therapy however she got a febrile recurrence with the same serological type of *E. coli*, O6:H7, now resistant to sulphonamide. This infection was treated with nitrofurantoin and the urine was again sterile. In connection with these two infections she was found to have a rather high antibody titre against the infesting strain and the decrease after treatment was very slow (Fig. 4).

She was readmitted in October 1962 by a practitioner who on repeated occasions had found her blood pressure to be 160/80. A hypertension could not be confirmed here and a re-investigation of her kidneys revealed nothing abnormal. However the coli antibody titre was still found to be increased and for this reason she has been seen regularly since then. Her urinary findings have on all occasions been normal without bacteriuria and she has been feeling well. Her blood pressure has been checked on several occasions and found to be somewhat elevated in the range of 140–165/90–105. IVP has been performed on three occasions. In January 1961 the right kidney was observed to be significantly smaller than the left and to have some calyceal dilatation. The findings were similar on the two following examinations in August 1965 and November 1966. Urethrocystography in January 1961 and August 1965 both showed vesico-ureteral reflux with pronounced dilatation of the ureter on the left side and discrete reflux on the right side. Reexamination of the patient in August 1965 showed a concentrating capacity of 1140 mOsm/l, specific plasma creatinine 0.8 mg per 100 ml and true endogenous creatinine clearance 121 l/24 h/1.73 m². In November 1966 the concentration capacity was unchanged, plasma creatinine 1.1 mg per 100 ml and creatinine clearance 105 l/24 h/1.73 m².

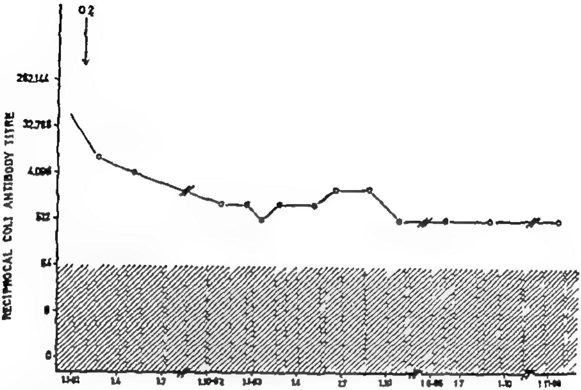

Fig 4 Coli antibody titres in patient *B W* originally infected with *E coli* O2:H7 and having one recurrence, caused by the same serotype. The antibody titre has remained elevated during an observation period of almost six years.

The patient was in repeated periods given sulphonamide up to half a year at the time. *Ampicillin* was given in two periods of two weeks. No effect on the antibody titre could be found after these therapeutic trials.

In summary this patient has had two attacks of acute pyelonephritis caused by the same serological type of *E coli* Since then she has had an elevated antibody titre against the infecting strain in spite of having no bacteriuria Some reduction of the renal parenchyma was observed in connection with the first known infection but this does not appear to progress Her blood pressure has a tendency to be elevated but returns to normal after a few days rest. The renal filtration is slightly reduced, but the concentration capacity normal

The findings in this patient are difficult to evaluate However it seems likely that there is some pathologic process in her renal parenchyma and that coli anti body production is still enhanced. Her tendency for elevated blood pressure makes it possible that she is at risk for having the same evolution of her pyelonephritis as demonstrated by the following patient, G.N

Hypertension

The diagnosis of the underlying disorder in patients with renal hypertension may often be difficult and there is thus a need for complementing procedures. So it was found of interest to see if determi nation of coli antibody titres in hyperten

sive patients were of any use. A series of patients were studied and the results will be published separately (1) The following case history will serve as an example

G N ♂ 11 03 44. At the age of two years this boy suffered from febrile urinary tract infection, caused by coliform bacteria. He was treated for two weeks with sulphonamide and the course was uneventful. A urinary culture performed two days after the cessation of therapy showed sterile urine. An IVP was normal.

During the following years he had several attacks of tonsillitis and at the age of ten he was treated for osteomyelitis. Routine investigations of the urine on several of these occasions revealed nothing abnormal. No cultures were performed, however

At the age of eleven years he was admitted to hospital for tonsillectomy His blood pressure was found to be elevated and he was referred to this hospital.

He was short and lean and had a blood pressure of 180/125 X-ray examination of the heart showed left-sided enlargement. Ophthalmoscopy revealed hypertensive changes of grade II III. Urinalyses Traces of protein, 0–4 leucocytes/mm^3 of uncentrifuged urine. Repeated quantitative urinary cultures <1000 bacteria/ml. Specific plasma creatinine 0.6 mg per 100 ml. True endogenous creatinine clearance 180 1/24 h/1 73 m^2 Maximal renal concentrating capacity 790 mOsm/l. IVP: Reduction of the renal parenchyma bilaterally together with calyceal dilatation. The changes were most pronounced on the right side.

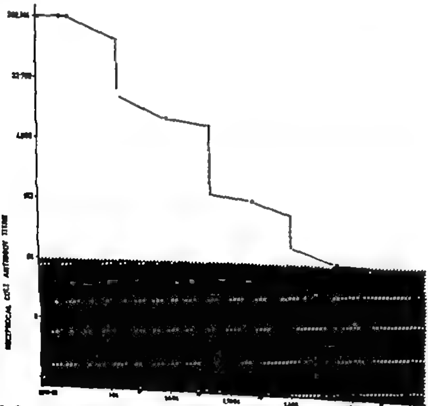

Fig. 5. Coli antibody titres in patient G. N with hypertension, probably caused by pyelonephritis. The antigen was in this case prepared from the patient's faecal coli strains.

As no bacteria were found in the urine, antigens were prepared from the patient's faecal coli flora and extremely high titres were demonstrated against these (Fig 5) Titrations were also performed in some of the serum samples from this patient with antigens derived from *E coli* 01 2 4 6 7 8 14 18 75 and 120 The antibody titres against 08 were similar to those obtained with the antigens derived from the patient faecal bacteria. The titres against the other 0 types were all 64 or less. It is thus most likely that the antibodies were elicited by *E coli* 08

The patient hypertension was treated with antihypertensive drugs continuously and he was further given sulphonamide for a period of about two years. He is still seen at regular intervals and his hypertension has stabilized at about 140/85. Urinary cultures performed at the check-ups have always been negative. There has been a slow but significant decrease of the antibody titre (Fig. 5)

The very frequent throat infections suffered by this patient arose the question of whether it could have been a covert glomerulonephritis which caused the hypertension. However the normal filtration, the slightly reduced concentration capacity and the roentgenologic findings made it more likely that the cause was a chronic pyelonephritis probably originating from his infection at two years of age This diagnosis is supported by the demonstration of an intense antibody response which decreased during chemotherapy

The reason for the long-standing elevations of the antibody titres in the preceding two patients is not quite clear As earlier pointed out the antibodies found with the haemagglutination method are mainly IgM and it must be assumed that antigens are still present in some form to stimulate the antibody producing cells. This may be in the form of a chronic infection with ordinary bacteria. It may also be caused by bacterial variants, not growing on the usual bacteriologic media Finally it may be caused by amorphous bacterial antigen remaining in the kidneys after an infection as recently found by Aoki and McCabe (2)

The findings in these patients indicate that determination of the antibodies may be an important tool as it seems to offer a possibility to detect some patients with early chronic pyelonephritis

Asymptomatic bacteriuria

So far there are very few reports of coli antibody determinations in patients with asymptomatic bacteriuria. In their extensive study of urinary tract infection in school children Kunin *et al* (17) determined the antibodies to *E coli* O-antigens in some of the bacteriuric children, but did not find significant elevations in any Percival *et al.* (20) found elevated antibody titres in 32 per cent of a group of pregnant women with asymptomatic bacteriuria

In the present study no systematic investigation of asymptomatic bacteriuria was attempted, but several titrations were performed in patients with asymptomatic recurrences found on routine examinations after acute urinary tract infections. In these situations elevated antibody titres were often found Examples of this were presented earlier (Fig 3 and Table III Cases 15 19 and VII 5)

Another patient with asymptomatic bacteriuria was found during the collection of samples from controls The case history is presented below

B. A. ♂ 62 11 30 The patient was readmitted at the age of five months for check-up after convulsions in the neonatal period, caused by minor cerebral bleeding. He was found to have slight neurologic sequelae, but was normal from other points of view He was af brile, had normal appetite and weight gain, haemoglobin 11.7 g per cent, ESR 4 mm/1 h. Urinary leucocyte count 14/mm³ Repeated quantitative urinary cultures revealed growths of 90,000–700,000 *E* coli/ml. His renal concentration capacity was 565 mOsm/l, which is slightly reduced with regard to the age (33). He was treated with sulphonamide, after which the urine was sterile and the concentration capacity rose to normal values. The coli antibody titres in this patient are presented in Fig 6 which shows an increased antibody titre when the disease was detected and normal fall after the treatment.

In spite of the complete absence of general symptoms it appears reasonable to believe that this patient was suffering from pyelonephritis because of the reduced concentration capacity and the elevated coli antibody titre.

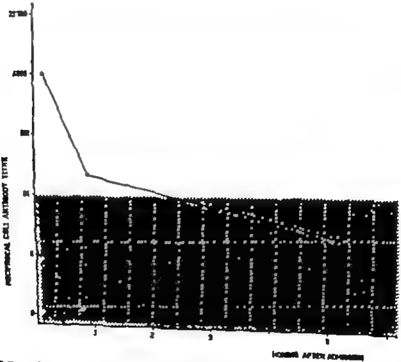

Fig. 6. Coli antibody titres in B. A., patient with asymptomatic bacteriuria, detected by a routine urinary culture.

SUMMARY

Earlier investigations have shown that the passive haemagglutination reaction is a specific and reliable tool in demonstrating humoral antibodies to different bacterial species.

In the first part of this survey some methodologic investigations are presented. It was found that the antibodies in the sera were partly or completely inactivated during storage at +4°C for about a month, while the activity was unchanged after at least six months at −20°C. The limiting concentration necessary for sensitization of the erythrocytes used in the reaction, was found to be around 60 million bacteria for different 0-antigens.

Four different sources of antigen were used during this investigation. Originally the infecting urinary bacteria from the patients were employed. Further studies compared this source with the faecal coli flora, with Kunin's common enterobacterial antigen and with a polyvalent antigen, consisting of a mixture of the eight *E. coli* 0-types most frequently encountered in urinary tract infections. The reason for these investigations were partly that some source other than urinary bacteria had to be used in the controls and in suspected cases of pyelonephritis without urinary excretion of bacteria, and partly that the preparation of individual antigens for each patient makes the method too complicated and time-consuming for use as a clinical routine procedure.

These studies revealed, that the faecal bacterial antigens gave results similar to the urinary ones in about half of the cases. The common enterobacterial antigen could not be used as a substitute for the homologous antigens since practically no antibodies were observed to this antigen in the sera. The polyvalent antigen was found to be a valuable substitute for the infecting strains, as equal titres could be demonstrated in those cases where the homologous urinary strains belonged to one or another of the types, included in the antigen pool. By means of this antigen it was also found that some patients, lacking antibody response to the bacterial strains, found in their urine, did have antibodies in elevated titres against the polyvalent antigen. This might be due to a continuous antigen stimulation from earlier infections. If this is proved, the finding indicates that determination of the coli antibody titre is a valuable tool in the detection of occult chronic pyelonephritis. However further studies are necessary to permit definite conclusions.

A material of controls was studied and it was found that almost all children above the age of about two months have agglutinating antibodies to *E. coli* in their serum.

A series of patients with uncomplicated first-time urinary tract infections with and without renal involvement were followed longitudinally. The findings showed that almost all of the patients above the age of three months with pyelonephritis had a sharp increase in the antibody titre, while those without functional impairment of the kidneys had titres within the limit of the control cases. It is thus possible to differentiate between cases of pyelonephritis and cases of lower urinary tract infections by means of this method. Elevated coli antibody titres were not

found in pyelonephritic patients below the age of two months. The reason for this is discussed.

A comparison between the antibody titre courses in patients with and without recurrences after their first episode revealed that the initial antibody response in the former group was not less than in the latter group

The rapid decrease (within 90 days) of the antibody titres found in most of the patients after treatment of the infections indicates that the homologous antigens were effectively eliminated by the treatment.

Determinations of the coli antibody titre were performed in some patients, whose clinical symptoms were suggestive of pyelonephritis, but in whom the usual urinary findings were absent or inconclusive. In eight out of thirteen of these a course of the antibody titre similar to that observed in patients with overt pyelonephritis was demonstrated and it is therefore regarded as most likely that these patients were in fact suffering from pyelonephritis.

Further the clinical use of antibody titrations in different types of urinary tract infections or their sequelae are illustrated by patients with recurrent urinary tract infection, renal hypertension and asymptomatic bacteriuria. The findings in some of these patients may indicate, that determination of antibodies to *E coli* is a useful instrument in the detection of some of those patients who are at risk for contracting chronic pyelonephritis.

SUMMARY

Earlier investigations have shown that the passive haemagglutination reaction is a *specific and reliable tool in demonstrating* humoral antibodies to different bacterial species.

In the first part of this survey some methodologic investigations are presented. It was found that the antibodies in the sera were partly or completely inactivated during storage at +4°C for about a month while the activity was unchanged after at least six months at −20°C. The limiting concentration, necessary for sensitization of the erythrocytes used in the reaction was found to be around 60 million bacteria for different 0-antigens

Four different sources of antigen were used during this investigation Originally the infecting urinary bacteria from the patients were employed Further studies compared this source with the faecal coli flora with Kunin's common enterobacterial antigen and with a polyvalent antigen, *consisting of a mixture of the eight E coli* 0-types most frequently encountered in urinary tract infections. The reason for these investigations were partly that some source other than urinary bacteria had to be used in the controls and in suspected cases of pyelonephritis without urinary excretion of bacteria and partly *that the preparation of individual anti*gens for each patient makes the method too complicated and time-consuming for use as a clinical routine procedure

These studies revealed that the faecal bacterial antigens gave results similar to the urinary ones in about half of the cases. The common enterobacterial antigen could *not* be used as a substitute for the homologous antigens since practically no antibodies were observed to this antigen in *the sera* The polyvalent antigen was found to be a valuable substitute for the infecting strains, as equal titres could be demonstrated in those cases, where the homologous urinary strains belonged to one or another of the types, included in the antigen pool. By means of this antigen it was also found that some patients lacking antibody response to the bacterial strains, found in their urine did have antibodies in elevated titres against the polyvalent antigen. This might be due to a continuous antigen stimulation from earlier infections If this is proved, the finding indicates that determination of the coli antibody titre is a valuable tool in the detection of occult chronic pyelonephritis. However further studies are necessary to permit definite conclusions.

A material of controls was studied and it was found that almost all children above the age of about two months have agglutinating antibodies to *E coli* in their serum.

A series of patients with uncomplicated first-time urinary tract infections with and without renal involvement were followed longitudinally The findings showed that almost all of the patients above the age of three months with pyelonephritis had a sharp increase in the antibody titre while those without functional impairment of the kidneys had titres within the limit of the control cases. It is thus possible to differentiate between cases of pyelonephritis and cases of lower urinary tract infections by means of this method Elevated coli antibody titres were not

QUANTITATIVE STUDIES OF THE HUMAN NEONATAL CIRCULATION

A collection of articles

edited by

GÖRAN WALLGREN M.D

STOCKHOLM 1967

FOREWORD

Among the many unsolved problems in modern pediatrics, those pertaining to the neonatal cardio-pulmonary adaptation have been intensely studied during the last decade. It is undoubtedly correct that neonatal mortality to a great extent is made up of infants who do not manage to successfully accomplish this adaptation and a study of these adaptive mechanisms consequently represents major challenge in neonatal research.

Although our knowledge regarding the idiopatic respiratory distress syndrome in the newborn infant has been enriched in some respects our overall concept of the etiology and pathophysiology of the disease is still defective. The need for more basic information with respect to the adaptive capacity of the normal newborn, premature and full term, is obvious before we will be able to delineate the characteristic picture of the circulatory and respiratory handicap of the infant developing the respiratory distress syndrome.

A circulatory parameter that has attracted great deal of interest in this respect is placental transfusion. Does the additional blood received by the infant immediately after delivery of the body have any physiological implications? Does this transfusion, which may amount to 30 % or more of the infants total blood volume improve its capacity to succeed in the mature circulatory achievement associated with adaptation to extrauterine life? During the last few years these questions have been studied in a research program conducted in our hospital and many pieces of information have been brought together. These studies have shown that there are considerable differences in the circulatory and metabolic patterns between infants with and without this transfusion. The fact that clinically infants deprived of the placental transfusion seem to do just as well, has suggested an impressive adaptive capacity of the vascular system which has also been supported from studies during induced hypovolemia. Although the healthy normal infant seems to cope with decreased initial blood volume without adverse consequences for the outcome of the extrauterine adaptation, the possibility exists that the olemic state may affect the outcome of this adaptation in the newborn infant with impaired organ function.

It is clear from previous studies of the hemodynamic response to neonatal hypovolemia that an integrated concept of the circulatory pattern without actual blood flow determinations is impossible as the adaptive procedures reflect changes in the interacting parameters of flow and resistance. The following series of articles is devoted to studies designed to quantitate cardiac output in the newborn infant with subsequent pplication to hemodynamic

FOREWORD

Among the many unsolved problems in modern pediatrics, those pertaining to the neonatal cardio-pulmonary adaptation have been intensely studied during the last decade. It is undoubtedly correct that neonatal mortality to great extent is made up of infants who do not manage to successfully accomplish this adaptation and a study of these adaptive mechanisms consequently represents a major challenge in neonatal research.

Although our knowledge regarding the idiopathic respiratory distress syndrome in the newborn infant has been enriched in some respects our overall concept of the etiology and pathophysiology of the disease is still defective. The need for more basic information with respect to the adaptive capacity of the normal newborn, premature and full term, is obvious before we will be able to delineate the characteristic picture of the circulatory and respiratory handicap of the infant developing the respiratory distress syndrome.

A circulatory parameter that has attracted great deal of interest in this respect is placental transfusion. Does the additional blood received by the infant immediately after delivery of the body have any physiological implications? Does this transfusion, which may amount to 50 % or more of the infants total blood volume improve its capacity to succeed in the massive circulatory achievement associated with adaptation to extrauterine life? During the last few years these questions have been studied in a research program conducted in our hospital and many pieces of information have been brought together. These studies have shown that there are considerable differences in the circulatory and metabolic patterns between infants with and without this transfusion. The fact that clinically infants deprived of the placental transfusion seem to do just as well, has suggested an impressive adaptive capacity of the vascular system which has also been supported from studies during induced hypovolemia. Although the healthy normal infant seems to cope with a decreased initial blood volume without adverse consequences for the outcome of the extrauterine adaptation, the possibility exists that the volemic state may affect the outcome of this adaptation in the newborn infant with impaired organ function.

It is clear from previous studies of the hemodynamic response to neonatal hypovolemia that an integrated concept of the circulatory pattern without actual blood flow determinations is impossible as the adaptive procedures reflect changes in the interacting parameters of flow and resistance. The following series of articles is devoted to studies designed to quantitate cardiac output in the newborn infant with subsequent application to hemodynamic

Indicator dilution techniques have won wide acceptance for a broad spectrum of cardiovascular clinical and research applications. Numerous communications have elaborated on the usefulness of this method for the estimation of cardiac output, as well as the detection and quantitation of intracardiac shunts and valvular defects. With very few exceptions these investigations were performed primarily on adult populations and, to some extent, on children above one year of age.

This report describes the various technical aspects involved in quantitative dye-dilution studies during the neonatal period. Methods, principles, instrumentation and calculations as adapted for use in this age group are presented, including an *in vivo* calibration technique, cardiac output estimation in the presence of left-to-right shunts, quantitation of arterio-venous (left-to-right) and veno-arterial (right-to-left) shunts and pulmonary blood volume. An integral factor implicit in such studies is employment of the so-called forward triangle method of dye curve analysis, and the following studies define a revised constant for such calculations in this particular age group.

Subjects, Procedure and Instrumentation

A total of 50 normal infants in the age range 2½—54½ hours forms the subject material for this and subsequent reports of newborn circulatory studies. The dye curves of 6 subjects without demonstrable shunt were utilized to derive a new forward triangle factor for cardiac output determination.

Following clinical examination of each infant, limb electrodes and a precordial microphone were applied for continuous electrocardiographic and phonocardiographic recording. The umbilical stump and surrounding skin were then thoroughly cleansed with PhisoHex® and Zephiran®. The umbilical stump was freshly cut, and two 5F infant feeding tubes 40 cm in length[1] were inserted into the umbilical vein and an umbilical artery. The venous catheter was advanced via the ductus venosus into the right atrium and subsequently through the foramen ovale into the left atrium. The arterial catheter was likewise advanced to a distance of 25—30 cm so that the tip lay approximately in the region of the aortic arch or root. (In 8 instances the catheter entered the pulmonary artery via the ductus arteriosus.)

The catheters were connected to EMT 35 strain gages,[2] and simultaneous recordings of pressure, electrocardiogram and phonocardiogram were made on the Mingograph 81 direct writing, 8-channel recorder.[2] Constant oscilloscopic monitoring of the electrocardiogram was conducted. Blood samples were analyzed for PO_2 using the Astrup Micro Equipment Model 22 with Clark oxygen electrode.[3] Radiologic methods were not employed in these infants. The catheter location was indicated by the distance of the catheter tip from the umbilical ring (compared with established anatomically-determined vascular distances (3)), the configuration of the pressure tracings, and the

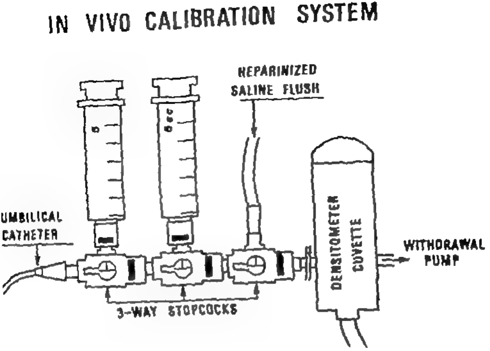

Fig. 1 Diagram illustrating sample arrangement for in vivo calibration of dye curves.

17 ml/min. A heparinized saline infusion system allowed flushing of the tubing and cuvette following reinfusion of blood to the infant upon completion of each dye curve. Saline remaining in the system was withdrawn by a separate syringe prior to the succeeding determination so that this added volume was not included in the withdrawal syringe and subsequently re-infused. Total dead space of venous and arterial catheters with connecting apparatus was 2.0 ml and was determined for each study. By virtue of this small dead space and use of a closed sterile system, blood loss was estimated to be less than 1.0 ml per curve recorded. A study comprising 20 curves, therefore, would result in slightly more than a 5 % blood volume reduction in a newborn infant over a period of 1—2 hours. Previous studies have shown (16) that even sudden volume depletions of this magnitude are well tolerated without extreme hemodynamic effects.

Due to the theoretical and practical objections to the use of placental blood obtained at delivery for dye-curve calibration, an *in vivo* method was developed which is both rapid and reliable. After all catheter connections had been made, the two 5 cc. syringes shown in Fig. 1 were filled with the infant's blood. Each syringe was in turn disconnected from its stopcock, air expelled, and the volume adjusted to exactly 5 cc. A Hamilton microsyringe of 50 µL capacity6 was used to dispense 25 and 50 µL of the 0.5 mg/ml. Cardio-green solution into the calibration syringes. The blood-dye mixtures were well agitated and the syringes reattached to the stopcocks. Since the plungers of the filled syringes were near the extreme

blood PO_2 values. The latter were particularly helpful in localizing the venous catheter at the left atrium or the arterial catheter at the pulmonary artery. In the final analysis, the contour as well as the appearance time of the arterial dye curves provided the best differentiation between left and right atrial catheter placement. Upon confirmation of the left atrial position of the catheter, the latter was secured by a purse-string suture to the umbilical stump.

A total of 140 normal newborns has been studied by umbilical catheterization in this facility according to the above procedure. In contrast to other reports (12), no febrile reactions, local or systemic infections occurred following these studies. One infant developed an umbilical hematoma which was noted to have resolved spontaneously at follow-up examination.

Dye-dilution Methodology

The umbilical catheter for injection of the indocyanine dye (Cardiogreen)[4] was attached by a system of 3-way stopcocks and Teflon tubing to a constant-volume injection syringe. Prior to the first dye curve, the catheter-stopcock-tubing system was filled with dye under positive pressure and the stopcock then closed until injection time. Failure to maintain positive pressure in the dye-filled catheter could result in retrograde displacement of dye, constituting a source of considerable error, particularly when injections are to be made into the arterial circuit. Despite this precaution, small amounts of dye will nevertheless be lost to the surrounding blood through capillary action and the effects of blood flow, and it thus is desirable to fill the catheter not more than 1 minute before intended injection. Estimation of this dye loss from an atrial catheter over a period of 3 minutes showed that approximately 3—5 % of the injected volume escaped from the catheter. Over a period of 1 minute, the loss of dye was insignificant.

Dye injection was accomplished manually by the operator who simultaneously pressed a signal button marking the recording. Flushing with saline was not done in this displacement method, a factor of importance in this age group for precisely timing the dye entrance into the circulatory system. An attempt was made to make the injection rate as uniform as possible to minimize variations on this basis. Similarly the operator, while watching the oscilloscopic electrocardiogram display, always tried to perform the injections at approximately the same point in the cardiac cycle during repeated determinations.

For the work under discussion, Cardiogreen in a concentration of 0.5 mg/ml was used, and an injection volume of 0.4 ml. This dosage of 0.2 mg dye per curve thus allowed registration of large numbers of curves without the risk of exceeding recommended limits of total dye administered.

The catheter employed for blood sampling, its tip usually situated in the proximal aorta, was connected by a series of 3-way stopcocks to the cuvette unit of a Waters X 301 densitometer[5] capable of background dye suppression up to a level of 36 mg/L. Response time for 67 % of final value with this instrument is 0.06 sec., and flow sensitivity is 97 % eliminated. The cuvette was in turn connected to a Sage-Waters constant speed infusion-withdrawal system which when fitted with a 20 cc. syringe withdrew sampling blood at a rate of 16—

representing the functional dead space rather than the actual or anatomic dead space (15).

The original constant described for the forward triangle was 0.37 (7). Subsequent evaluation of the method (1) suggested that this should be revised to 0.34 in order to provide better correlation with the Hamilton method of total curve analysis. In both the original and later studies, the subject material was composed of adults, and many cases of acquired and congenital cardiac disease were included. In addition, the vast majority of dye curves was recorded following peripheral injection and/or sampling of dye.

It was with the constant 0.34 that we initiated our quantitative studies. After analysis of the recordings from several neonates, the suspicion arose that the forward triangle portion of these curves did not constitute 34 % of the total curve. It was felt that the factors of central injection and sampling, coupled with the very rapid circulation times, significantly altered this relationship. A relatively small ejection fraction (stroke volume/end-diastolic volume)

limit of their travel they could easily be removed despite the closed position of the stopcocks. Blood was then drawn through the densitometer from the infant for zero base line and subsequently from the two syringes to provide deflections corresponding to 2.5 and 5.0 mg/L. All blood was then re-infused. The system was originally planned to enable registration of 4 or more calibration points by simply repeating the procedure. However it was noted that the calibration factors corresponding to the 2.5 and 5.0 mg/L concentrations did not differ significantly in the same baby (error = 2.8 %, n = 25). Densitometer linearity was consistently established by this method, a result which we often had difficulties achieving when using placental blood.

With this means of calibration we have found that the calculated calibration factor varies considerably from infant to infant. In 25 consecutive calibrations the deflections corresponding to 5.0 mg/L varied between 162 and 198 mm, a range of 0.0254 to 0.0309 mg/L/mm for the constant. This represents a 20 % difference of the mean of these 25 values. This varies somewhat from previous reports (5) in which placental blood was used for densitometer standardization.

Calibrations and dye curves were recorded on a direct writing recorder[7] at a paper speed of 10 in./min. (4.23 mm/sec.) Paper width was 250 mm. The recorder was linear over the entire range of pen travel and 90 % response time for a full scale deflection was 0.■ sec. Depending on injection and sampling sites, peak concentration of dye curves varied between 130 and 220 mm or 3.8 to 6.5 mg/L at the recorder sensitivity employed.

Quantitation of Dye Curves

Due to the very frequent presence of circulatory shunts in the early newborn period, evaluation of dye curves by the standard Hamilton method (9) is often impossible. Distortion of the primary curve along its exponential decay portion may occur very shortly after peak concentration has been attained due to the unusually rapid circulation time. Logarithmic extrapolation of the downslope is therefore obviated.

In order to overcome such difficulties which are also inherent in curves from patients with valvular regurgitation or cardiac decompensation, Hetzel et al. (7) investigated the possibility of evaluating any dye curve through its initial portion up to the point of peak concentration. This forward triangle method has since found wide application for estimation of cardiac output, not only from "problem" curves, but also as a relatively easy and time-saving method in itself. The derived values for cardiac output so obtained and the associated range of variability are generally considered to validate the method. The basic formula employs values for the time from curve appearance to peak concentration (build-up time, BT), the peak concentration itself (PC), the amount of injected dye (I) and a factor K, determined by the authors. The relationship of these factors is expressed by

$$\text{Cardiac output} = \frac{60\ I}{0.5\ (PC)\ (BT)} \times K$$

A sample calculation with the derivation of necessary values is given in Fig. 2. The factor of 0.6 appearing in the formula for dead space in this Figure is a correction factor relating the parabolic distribution of dye particles in the moving column of blood along the catheter-cuvette tubing assembly.

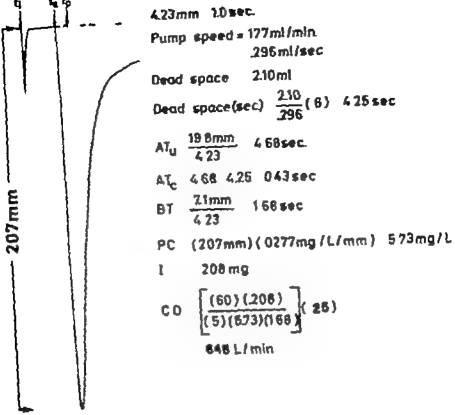

Fig Dye curve calculations AT_u = uncorrected appearance time AT_c = corrected appearance time BT = build up time PC = peak concentration I = injectate CO = cardiac output t_i = injection time t_a = appearance time t_p = peak concentration time The interval between two heavy time lines = 1 inch or 6 sec

representing the functional dead space rather than the actual or anatomic dead space (15).

The original constant described for the forward triangle was 0.37 (7). Subsequent evaluation of the method (1) suggested that this should be revised to 0.34 in order to provide better correlation with the Hamilton method of total curve analysis. In both the original and later studies, the subject material was comprised of adults, and many cases of acquired and congenital cardiac disease were included. In addition, the vast majority of dye curves was recorded following peripheral injection and/or sampling of dye.

It was with the constant 0.34 that we initiated our quantitative studies. After analysis of the recordings from several neonates, the suspicion arose that the forward triangle portion of these curves did not constitute 34% of the total curve. It was felt that the factors of central injection and sampling, coupled with the very rapid circulation times, significantly altered this relationship. A relatively small ejection fraction (stroke volume/end-diastolic volume)

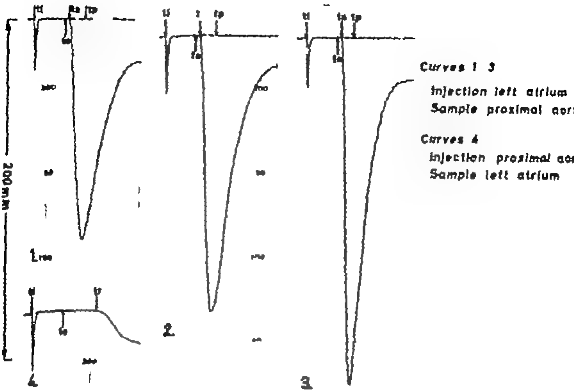

Fig 3 Series of 3 dye curves resulting from left atrial injection and a fourth ... from aortic injection and left atrial sampling Curve 4 indicates absence of left-to-right ductal shunt Variation in cardiac output of curves 1—3 is secondary to hemodynamic changes intentionally induced during study Symbols as in Fig

in neonates could also be an important consideration in this regard

To clarify this problem, a total of 55 dye curves was recorded following left atrial injection and proximal aortic sampling in 6 infants aged 27 to 54 hours (mean 44 4 hours) All curves contained a minimum of 4 points on the exponential decay segment prior to onset of re-circulation which were in linear relationship when plotted logarithmically Many exhibited 5—6 such points. Absence of left-to-right ductus arteriosus shunt was attested to by the lack of a densitometer response prior to recirculation after injection in the proximal aorta and sampling in the left atrium (see Curve 4 Fig 3) This is in conformity with the studies of Moss et al (11) in which a ductal shunt was usually no longer demonstrable by blood gas analysis after 15 hours of age in normal term infants. It is possible however that a small L R shunt through the foramen ovale may occur if the left atrial catheter displaces the foramen valve Such a small shunt, which might not produce an obvious recirculation peak on the primary curve would also not be detected by aortic injection with left atrial sampling There does not appear to be a convenient method for detecting such a hidden shunt short of left atrial injection with right atrial sampling, and the possible presence of this

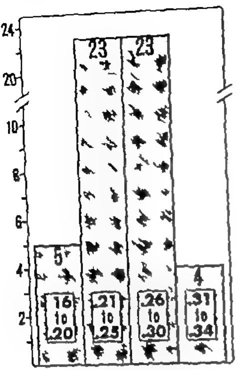

Fig. 4 Frequency distribution of forward triangle factor K, calculated from dye curves with left atrial injection and proximal aortic sampling in normal newborn infants.

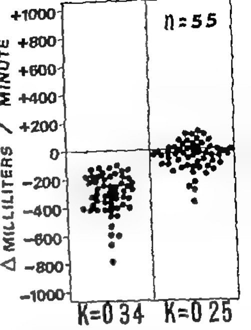

Fig. 5 Frequency distribution of differences in cardiac output calculated by Hamilton re-plot method and forward triangle method using factors 0.34 and 0.25 for the latter. Mean difference for 0.34 factor is −0.311 L/min. and for the 0.25 factor is −0.051 L/min.

catheter-induced artifact, therefore, represents an inherent but probably minor imperfection of the dye-dilution method.

The mean value of the forward triangle area relative to total curve area was 0.25 ± 0.005 S.E. for the left-atrial injection studies. This represents a 24% reduction of the 0.34 figure developed in adults. Frequency distribution of the individual constants calculated is represented in Fig. 4. When the 55 left-atrial curves were recalculated with the new factor of 0.25 instead of 0.34, the mean difference between cardiac output determined by the Hamilton and by the forward triangle methods decreased from −0.311 L/min. to −0.051 L/min. This is presented graphically in Fig. 5. Despite the obviously much-improved correlation of output values derived by the two methods when employing the 0.25 forward triangle factor, it is apparent that isolated instances of wide divergence still exist. This limits the reliance which may be placed on a single determination, and indicates that duplicate or even triplicate curve recordings should be carried out when feasible.

The reproducibility of cardiac output estimation by this method is surprisingly good (6, 13) particularly when determinations are performed with only 2—3 minutes delay between individual curves. This is illustrated in Fig. 6 and Fig. 7 for curves

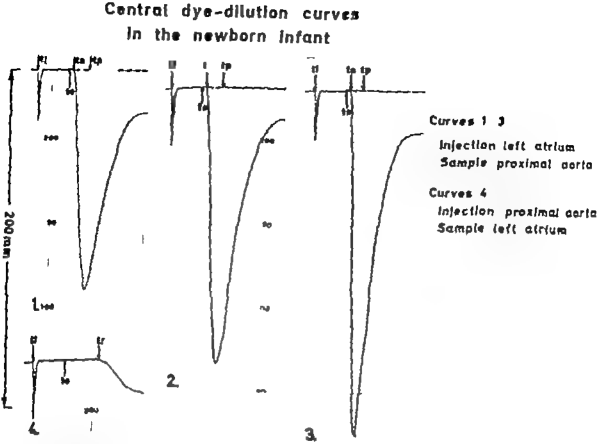

Fig 3 Series of 3 dye curves resulting from left atrial injection and a fourth curve from aortic injection and left atrial sampling. Curve 4 indicates absence of left-to-right ductal shunt. Variation in cardiac output of curves 1—3 is secondary to hemodynamic changes intentionally induced during study. Symbols as in Fig 2

in neonates could also be an important consideration in this regard.

To clarify this problem, a total of 55 dye curves was recorded following left atrial injection and proximal aortic sampling in 6 infants aged 22 to 54 hours (mean 44.4 hours). All curves contained a minimum of 4 points on the exponential decay segment prior to onset of re-circulation which were in linear relationship when plotted logarithmically. Many exhibited 5—6 such points. Absence of left-to-right ductus arteriosus shunt was attested to by the lack of a densitometer response prior to recirculation after injection in the proximal aorta and sampling in the left atrium (see Curve 4 Fig 3). This is in conformity with the studies of Moss et al (11) in which a ductal shunt was usually no longer demonstrable by blood gas analysis after 15 hours of age in normal term infants. It is possible, however, that a small L-R shunt through the foramen ovale may occur if the left atrial catheter displaces the foramen valve. Such a small shunt, which might not produce an obvious recirculation peak on the primary curve, would also not be detected by aortic injection with left atrial sampling. There does not appear to be a convenient method for detecting such a "hidden" shunt short of left atrial injection with right atrial sampling, and the possible presence of this

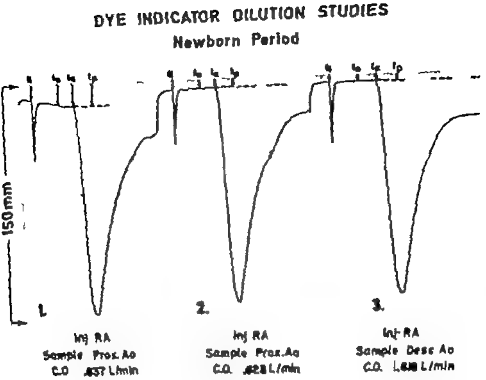

Fig. Three consecutive right-atrial-injection curves made at 2-minute intervals to demonstrate reproducibility of the method for cardiac output estimation.

ber the shunt will appear on the decay portion of the curve (Curve 1 Fig 8)

Calculation of left-to-right shunt employs an extension of the forward triangle method and is based on the assumption that the area under the peak of the shunt curve is inversely proportional to shunt flow while the area under the primary peak is inversely proportional to right ventricular output. Several factors must be extracted from the curve for this calculation, namely appearance and build-up times of the shunt and primary curves, and peak concentrations of both curves. In addition, the pulmonary circulation time must be known to enable derivation of the build-up time of the shunt curv

Pulmonary circulation time (PCT) is reflected in the difference in the appearance times of the curves following right atrial (or right ventricular) injection and left atrial injection using the same arterial sampling site. Change of the catheter injection sites should be as rapid as possible to minimize errors from an unsteady state. In the presence of a left-to-right ductal shunt, dye injection in the aortic root and left atrial sampling also indicates the PCT the appearance time of the dye curve representing the shortest traversal time of the dye across the aorta, ductus, pulmonary vascular bed and left atrium. Similarly if the aortic catheter has entered the pulmonary artery through the ductus, injection may be made

derived from left and right atrial injections, respectively The close agreement of values for pulmonary blood flow in curves 1 2 3 and 3 4 of Fig 6 (representing two sets of physiological conditions) and of all three curves of Fig 7 is apparent. It is, of course, necessary to pay strict attention not only to the quiescent state of the infant but also to the rapid variation in heart rate when comparing flow estimations, and simultaneous recording of electrocardiogram and dye curves is essential for intelligent interpretation of results.

Shunt Estimation

In common with recently published reports (10) we have made use of a modification of a method suggested by Swan et al. (14) for left-to-right extra-cardiac shunt quantitation Since the pulmonary circulation time in the newborn is characteristically very rapid, it is impossible to make use of dye curves from right-atrial injections because the shunt will appear mixed in the primary curve before peak concentration is reached For this reason, ductal shunt may be calculated only after left-atrial injection

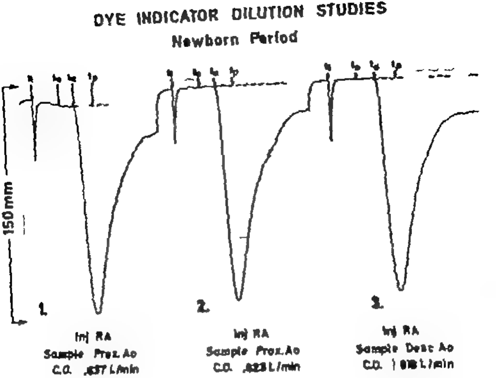

Fig. 7. Three consecutive right-atrial-injection curves made at [illegible]-minute intervals to demonstrate reproducibility of the method for cardiac output estimation.

where the shunt will appear on the decay portion of the curve (Curve 1 Fig. 8).

Calculation of left-to-right shunt employs an extension of the forward triangle method and is based on the assumption that the area under the peak of the shunt curve is inversely proportional to shunt flow while the area under the primary peak is inversely proportional to right ventricular output. Several factors must be extracted from the curve for this calculation, namely appearance and build-up times of the shunt and primary curves, and peak concentrations of both curves. In addition, the pulmonary circulation time must be known to enable derivation of the build-up time of the shunt curve.

Pulmonary circulation time (PCT) is reflected in the difference in the appearance times of the curves following right-atrial (or right ventricular) injection and left atrial injection using the same arterial sampling site. Change of the catheter injection sites should be as rapid as possible to minimize errors from an unsteady state. In the presence of a left-to-right ductal shunt, dye injection in the aortic root and left-atrial sampling also indicates the PCT the appearance time of the dye curve representing the shortest traversal time of the dye across the aorta, ductus, pulmonary vascular bed and left atrium. Similarly if the aortic catheter has entered the pulmonary artery through the ductus, injection may be made

DYE INDICATOR DILUTION STUDIES

Newborn Period

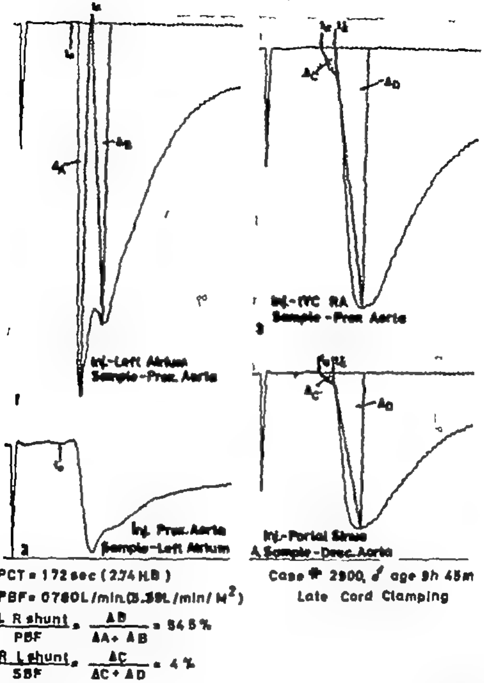

Fig. 8. Dye curves recorded from various injection and sampling sites exhibiting left-to-right and right-to-left shunt and method of shunt calculation. t_o = corrected appearance time. t_a = L R shunt appearance time. t_a = R L shunt appearance time. t_j = appearance time of primary curve. H.B = heart beats.

at the former site and sampling performed in the left atrium. A comparison of the PCT's obtained by the first two methods was made in 12 infants. A mean value and standard error of 2.01 ± 0.05 sec. was obtained for the PCT derived from the combined *right* and *left-atrial* injection curves, while corresponding figures for aortic injection with *left-atrial* sampling were 1.85 ± 0.11 sec. ($r = 0.63$). Obviously PCT must be established for each individual rather than attempting to apply a mean value.

Once the estimation of PCT has been made, the remaining factors necessary for the shunt formula are easily obtained. With reference to Curve 1 Fig. 8, the time of shunt appearance, t_a, is located as the difference between the peak concentration time of the shunt and PCT. Build-up time of the shunt and primary curves are then measured as are their peak concentrations. The latter may be expressed, with linear densitometer response, in millimeters of deflection without conversion to corresponding mg/L concentration, since the calibration factor mg/L/mm cancels out in the formula where shunt is expressed as a fraction of total pulmonary blood flow (PBF)

$$\frac{\text{L-R shunt}}{\text{PBF}} = \frac{(BT_s)\ (PC_s)}{(PC_1)\ (BT_1) + (BT_s)\ (PC_s)}$$

or referring to Fig. 8 again

$$\therefore \text{L-R shunt} \approx \frac{\text{area B}}{\text{area A} + \text{area B}}$$

Theoretically it may be stated that this method of shunt estimation is not entirely valid because the shunt curve's peak concentration, PC_s, actually represents a summation effect of primary curve and shunt curve, not the shunt curve effect alone. This consideration is diagrammed in Fig. 9 to illustrate that PC_s is actually the height to which the primary curve's decay portion is deflected by the peak concentration of a simultaneously-occurring curve due solely to true shunt. The finding that the magnitude of a L-R shunt can be estimated fairly accurately (10) by the equation above is probably due to area B's appearance in both numerator and denominator and the frequent appearance of shunt effect relatively low on the rapidly falling primary curve, thus tending to minimize the difference between *true* shunt curve PC and that measured for use in the formula. Were it possible to establish the primary curve exponential decay, true shunt PC could then be measured (dimension X, Fig. 9), but this is usually impossible.

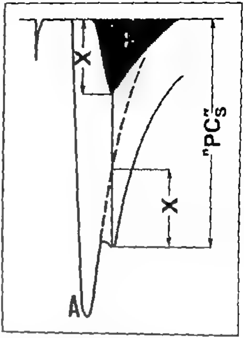

Fig. 9. Illustrating that actual shunt curve B (cross-hatched area) displaces primary curve A decay portion (dashed line) by height X. Dimension PC_s, therefore, does not represent actual peak concentration of shunt but its effect on the primary curve. Recirculation is not depicted.

triangle is but one example of this. An analogous situation occurred with regard to shunt calculations by Carter's formulae (2) where it was found that significant over estimation of shunt existed by virtue of extremely early appearance of ductal flow in the dye curve.

SUMMARY

Principles and techniques for the application of indicator-dilution studies to the newborn period are discussed. A simple method for *in* [illegible] dye curve calibration is described, and a modification of the forward triangle factor for cardiac output estimation in this age group is presented. Methods of calculation of cardiac output and shunts are given. Many problems unique to the neonatal period are suited to study by careful application of these techniques.

ACKNOWLEDGEMENT

The authors wish to express their appreciation of the invaluable technical assistance given by Mrs. Ulla Führer, Mrs. Ingrid Werner and Mrs. Signe Bergströmer

Another theoretic consideration limiting the reliability of shunt estimation by this method concerns the validity of applying a primary curve forward triangle factor of 0 25 to the shunt curve Almost certainly differences in circulation transit times produce a shunt curve forward triangle area which represents more than 25 % of the total curve. This undoubtedly introduces some error into the shunt quantitation method outlined above. Nevertheless, as has been demonstrated despite these inconsistencies, meaningful evaluation of shunt magnitude can be accomplished (10) by means of the simple dye-curve measurements described

The magnitude of right to-left shunting is evaluated in a similar manner (Curve 2 Fig. 8) Appearance time of the primary curve, t_{a} is estimated from the PCT and the areas of shunt and primary curves are obtained as above

In dye-dilution curves with ductus arteriosus left to-right shunt only and no other intracardiac shunt PBF equals left ventricular output (LVO) Since the ductal shunt is expressed as a fraction of PBF right ventricular output (RVO) is derived according to the following relationships as modified from Gessner et al (5)

$$PBF = RVO + L\ R \text{ shunt}$$

$$PBF = RVO + \frac{(\%\ L\ R)}{100}\ (PBF)$$

$$RVO = PBF - \frac{(\%\ L\ R)}{100}\ (PBF)$$

Since $LVO = PBF$

$$RVO = LVO - \frac{(\%\ L\ R)}{100}\ (LVO) =$$

ESBF (effective systemic blood flow)

Miscellaneous Calculations of Interest

Systemic circulation time may be derived from the aorta to-left atrium curves The PCT derived as previously discussed, is then subtracted from the aorta to-left atrium circulation time.

An approximation of pulmonary blood volume may be made using the parameters of PBF PCT injected amount of dye and peak concentration of the dye curve following pulmonary artery injection with left atrial sampling These factors are related by the expression (8)

$$PBV = \frac{(PBF)\ (PCT)}{60} + \frac{I}{PC}$$

DISCUSSION

The recent interest accorded the human organism's adaptation to extra-uterine life has far-reaching consequences. Studies centered on the neonatal period are of great importance not only for the establishment of normal values but also as the basis for investigating disease states and devising therapeutic programs. Examples of such applications may be found in answering questions relative to early versus late umbilical cord clamping and study of the respiratory distress syndrome The newborn infant can by no means be considered a micro version of the adult, and consequently mere miniaturization or direct transference of examination techniques valid for the adult may not pertain.

These considerations have been substantiated repeatedly during the performance of indicator-dilution studies in newborn infants. Extremely rapid circulation times and the frequent presence of shunts have required alteration of previously accepted methods. The modification of the forward

triangle is but one example of this. An analogous situation occurred with regard to shunt calculations by Carter's formulae (2) where it was found that significant over estimation of shunt existed by virtue of extremely early appearance of ductal flow in the dye curve.

SUMMARY

Principles and techniques for the application of indicator-dilution studies in the newborn period are discussed. A simple method for [illegible] dye curve calibration is described, and a modification of the forward triangle factor for cardiac output estimation in this age group is presented. Methods of calculation of cardiac output and shunts are given. Many problems unique to the neonatal period are suited to study by careful application of these techniques.

ACKNOWLEDGEMENT

The authors wish to express their appreciation of the invaluable technical assistance given by Mrs. Ulla Föhrer, Mrs. Ingrid Werner and Mrs. Signe Bergströmer

Interest in the circulatory dynamics of the newly born infant has increased in recent years. Cardiac catheterization, chiefly intracardiac pressure measurements and blood gas analyses, have been performed during the first hours or days of life (1 3, 8, 20 21). However cardiac output, shunt flow quantitation, and vascular resistance have generally not been determined due to technical difficulties.

The cardiovascular status of the neonate (9 18) has also been evaluated by the dye indicator dilution technic. Recent studies show that in the neonate with left-to-right shunt, peripheral venous or even right heart dye injection is not reliable for cardiac output estimation because of the very rapid pulmonary circulation time (9 13).

This communication presents the results of two-catheter dye dilution studies in 11 newborn infants with early clamping of the umbilical cord and in 36 infants with delayed clamping of the cord. Previous studies (17 26) have established significant differences in the blood volumes of these two groups, presumably related to the magnitude of placental transfusion. This investigation was initiated to determine the influence of perinatal placental blood transfer on the cardiovascular adjustments after birth.

MATERIAL AND METHODS

Forty-seven normal, term, newborn infants were studied by cardiac catheterization and dye indicator dilution technic. The subjects were classified into two groups according to the time at which the umbilical cord was clamped (1) *early* clamp group (EC) where the cord was clamped within 2 to 10 seconds after delivery of the trunk and, (2) *late* clamp group (LC) where the cord was clamped after cessation of the umbilical artery pulsations, generally 3 to 5 minutes after birth.

The EC group comprised 11 infants 2¾ to 12½ hours old at the time of the indicator dilution study. There were 7 males and 4 females with a mean birthweight of 3 39 kg (range 2.68 to 3.80 kg). The LC group comprised 36 infants 2½ to 54 hours of age. There were 20 males and 16 females. Their mean birthweight was 3 70 kg (range 3.04 to 4.87 kg). The difference in the mean birthweights was significant ($P<0.02$)

All subjects were products of uneventful pregnancies. Delivery was uncomplicated and through the vaginal route in cephalic presentation. Pethidine in dosages of 50 to 150 mg was administered intramuscularly to 6 mothers (2, EC group 4, LC group) several hours before delivery. Nitrous oxide was administered intermittently to 15 mothers (6 EC group 9 LC group). All infants cried spontaneously after birth, and none required resuscitation. No cardiopulmonary abnormality was observed clinically. With the exception of 14 LS infants over 14 hours of age, all infants were studied prior to their first feeding. No anesthesia, antibiotics, or other medication was employed. Room temperature was 25°C to 26°C, and all subjects breathed room air. No complications related to the procedure occurred aside from a mild umbilical stump

hematoma in one subject which resolved spontaneously

Cardiac catheterization was performed by the transumbilical approach A 5-F soft polyvinyl catheter[1] with two side holes 6 mm apart near its tip was inserted into the umbilical vein, and another into an umbilical artery They were gently advanced centrally into the cardiac chambers without fluroscopic guidance. Intracardiac and vascular pressures were recorded and blood samples obtained for gas analysis Catheter position was indicated by the distance of the tip from the umbilical ring, the pressure curve, the blood gas findings, and the configuration and appearance time of the dye curves Upon establishment of the desired intracardiac position of the catheter the latter was secured by a purse-string suture to the umbilical stump The technic has been described previously (3)

A three way stopcock connected the injection catheter to a 10 ml reservoir syringe containing 0 5 mg/ml dye solution (Cardiogreen®)[2] and to a 2 ml syringe adjusted to deliver a constant volume of 0 4 ml Immediately preceding each injection, the catheter and delivery syringe were filled under positive pressure from the 10-ml reservoir Special care was taken to eliminate air bubbles. The dye thus delivered by volume displacement, was injected manually the operator simultaneously pressed a signal button to record the instant of injection.

The sampling catheter was connected to the cuvette unit of a Waters X 301 densitometer with a Teflon tubing The volume of this catheter to-cuvette assembly ranged from 1 5 to 2 0 ml. During the inscription of the dye curve, blood was withdrawn with a Sage Waters withdrawal infusion pump into a 20-ml lubricated heparinized syringe at a rate of 16 to 17 ml/min. It was re infused into the baby immediately afterward A Sargent direct writer recorded galvanometer deflections at a paper speed of 10 in/min. (4 23 mm/sec.) Response time for 90 % of full scale deflection was 0 9 second Densitometer and recorder response was linear in the range of dye concentrations used and over the entire range of pen travel

The appearance time was corrected for catheter delay time (25) (see Appendix I) In the first 16 cases cord blood in three dye concentration ranges was used for calibration. In the subsequent cases, an *in vivo* calibration method was used prior to the actual dye curve studies (11) Two 5-ml samples of the baby s blood were withdrawn into heparinized syringes 25 and 50 µL of dye solution were added with a Hamilton microsyringe to yield a concentration of 2.5 and 5 0 mg/L, respectively The syringes were connected in series to the arterial catheter by two three-way stopcocks. Blood was drawn from the infant to establish the zero baseline and subsequently from each syringe (with plunger removed) All blood was then immediately re infused The calibration factor converted recorded deflection in millimeters into dye concentration in milligram per liter of blood

Cardiac output and left to-right shunts were determined by injection into the left atrium and sampling from the aorta proximal to the ductus arteriosus In 4 cases, sampling was from the descending aorta alone. In 8 infants, the injection and sampling sites were the pulmonary artery and left atrium, respectively Right to-left atrial shunting was determined by injecting the dye into the right atrium and sampling from the proximal aorta. The procedure was re

hematoma in one subject which resolved spontaneously

Cardiac catheterization was performed by the transumbilical approach. A 5 F soft polyvinyl catheter[1] with two side holes 6 mm apart near its tip was inserted into the umbilical vein, and another into an umbilical artery. They were gently advanced centrally into the cardiac chambers without fluroscopic guidance. Intracardiac and vascular pressures were recorded and blood samples obtained for gas analysis. Catheter position was indicated by the distance of the tip from the umbilical ring, the pressure curve, the blood gas findings, and the configuration and appearance time of the dye curves. Upon establishment of the desired intracardiac position of the catheter the latter was secured by a purse-string suture to the umbilical stump. The technic has been described previously (3).

A three way stopcock connected the injection catheter to a 10-ml reservoir syringe containing 0.5 mg/ml dye solution (Cardio-green®)[2] and to a 2 ml syringe adjusted to deliver a constant volume of 0.4 ml. Immediately preceding each injection, the catheter and delivery syringe were filled under positive pressure from the 10-ml reservoir. Special care was taken to eliminate air bubbles. The dye, thus delivered by volume displacement, was injected manually, the operator simultaneously pressed a signal button to record the instant of injection.

The sampling catheter was connected to the cuvette unit of a Waters X 301 densitometer with a Teflon tubing. The volume of this catheter-to-cuvette assembly ranged from 1.5 to 2.0 ml. During the inscription of the dye curve, blood was withdrawn with a Sage Waters withdrawal infusion pump into a 20-ml lubricated heparinized syringe at a rate of 16 to 17 ml/min. It was re-infused into the baby immediately afterward. A Sargent direct writer recorded galvanometer deflections at a paper speed of 10 in/min. (4.23 mm/sec.). Response time for 90 % of full scale deflection was 0.9 second. Densitometer and recorder response was linear in the range of dye concentrations used and over the entire range of pen travel.

The appearance time was corrected for catheter delay time (25) (see Appendix I). In the first 16 cases, cord blood in three dye concentration ranges was used for calibration. In the subsequent cases, an *in vivo* calibration method was used prior to the actual dye curve studies (11). Two 5 ml samples of the baby's blood were withdrawn into heparinized syringes. 25 and 50 µL of dye solution were added with a Hamilton microsyringe to yield a concentration of 2.5 and 5.0 mg/L, respectively. The syringes were connected in series to the arterial catheter by two three-way stopcocks. Blood was drawn from the infant to establish the zero baseline and subsequently from each syringe (with plunger removed). All blood was then immediately re-infused. The calibration factor converted recorded deflection in millimeters into dye concentration in milligram per liter of blood.

Cardiac output and left-to-right shunts were determined by injection into the left atrium and sampling from the aorta proximal to the ductus arteriosus. In 4 cases sampling was from the descending aorta alone. In 8 infants, the injection and sampling sites were the pulmonary artery and left atrium, respectively. Right-to-left atrial shunting was determined by injecting the dye into the right atrium and sampling from the proximal aorta. The procedure was re

F 1 Dye dilution curves of 9-¾-hour old male LC infant with bidirectional shunts. The pAo → LA run (No. 2) confirms the ductal (arteriosus) shunt and shows PCT of 1.72 seconds. The estimated left-to-right shunt ($\frac{\Delta B}{\Delta A+\Delta B}$) was 54.5% of pulmonary blood flow; the estimated right-to-left shunt ($\frac{\Delta C}{\Delta D+\Delta C}$) was 4% of systemic flow. Pulmonary blood flow was 3.39 L/m/M²

Circles = LC infants

peated using the descending aorta as the sampling site for detection of ductal (or combined ductal and atrial) right-to-left shunting In the cases showing a shunt by the latter technic, right ventricular injection to confirm the ductal origin of the shunt was not done due to failure to advance the venous catheter into the right ventricle

Cardiac output was calculated by the forward triangle method (5 12) with some modification (see Appendix II) The estimated output value of each case represented the average of 2 to 6 or more, dye curves. In 6 LC infants aged 22 to 54 hours (mean 44 4 hours) without demonstrable shunt, a total of 35 left atrial-to-proximal aortic (LA → pAo) dye curves was obtained to derive the K factor for the forward triangle method.

A left-to-right shunt was indicated by a secondary deflection appearing early in the disappearance slope of the curve and separate from that of the recirculation curve (fig 1) The origin of this shunt from a patent ductus arteriosus was confirmed by reversing the injection and sampling sites i e by injecting the dye into the aorta pro

arterial in the ductus and sampling from the left atrium. Quantitation of the left-to-right shunt was made from the LA → pAo and from the pulmonary artery-to-left atrial (PA → LA) dye curves (see Appendix III). Systemic blood flow was also estimated, and the corresponding pulmonary/systemic flow ratio was derived (fig. 2). Pulmonary and systemic vascular resistances were also computed using the standard formula

$$\text{Pulmonary P.R.U.} = \frac{PA_m - LA_m \text{ (in mm Hg)}}{Q_p \text{ (per M}^2\text{ of B.S.A.)}}$$

$$\text{Systemic P.R.U.} = \frac{Ao_m - RA_m \text{ (in mm Hg)}}{Q_s \text{ (per M}^2\text{ B.S.A.)}}$$

A right-to-left shunt was indicated by an abnormally short appearance time and an early hump in the build-up slope of the right atrial-to-aortic dye curve (Fig. 1). The size of the shunt was estimated by Swan's method (23), but the theoretical appearance time of the primary curve was estimated from the pulmonary circulation time (see Appendix IV).

The pulmonary circulation time (PCT) was indicated by the appearance time of the PA → LA dye curves. In neonates with left-to-right ductal shunts, the appearance time of the pAo → LA dye curves also yielded the PCT since the shunt pathway consisted of the ductus and pulmonary vascular bed. The PCT was also indirectly indicated by the difference in the appearance times of the right and left-atrial injection dye curves using the same aortic sampling site. The latter values actually measured the right atrium-to-left atrium circulation time.

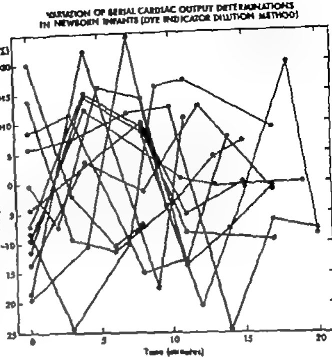

Fig 4 Serial cardiac output determinations of newborn infants at rapid intervals. Each dot represents the per cent difference of single output from the mean of the respective series 0 minute refers to the first determination

Functional patency of the ductus venosus was investigated by umbilical venous injection and subsequent right atrial injection. A constant sampling site consisting of either the pulmonary artery or the aorta was used (fig 3)

RESULTS

The reproducibility of the dye curves is illustrated in figure 4, where the individual cardiac output values have been plotted as percent difference from the mean output of each series One standard deviation of the percentile variation about the mean was ±11.75%

The indirect PCT derived from the RA and LA injection curves showed fair correlation with that obtained by the corresponding pAo → LA and PA → LA curves ($r = +0.63$) The average PCT for all subjects was 1.86 seconds ±0.46 S.D (range 0.9 to 2.4 seconds) 1 There was no appreciable difference between the early and the late age groups, or between the EC and LC subjects. Pulmonary circulation time was also converted into heart beats by the equation

$$H.B = PCT \times \frac{\text{heart rate/min.}}{60}$$

This averaged 3.59 heart beats ±0.925 S.D with a range of 1.65 to 5.0 heart beats (fig 5)

Table 1 is a summary of the heart rate, left ventricular stroke volume, left ventricular output (numerically equivalent to

The PCT derived from the RA and LA injection curves was utilized only in those without sharp onset of the PA → LA or pAo → LA curves. None had right-to-left shunts.

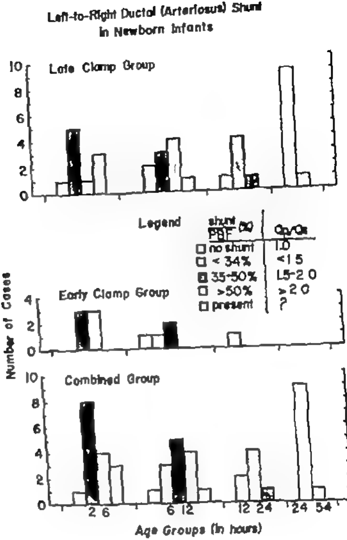

Fig 6 Relative frequency of left-to-right shunts in the newborn period.

Of the 7 infants aged 12½ to 24 hours, a left-to-right shunt was observed in 5. In one of these, a 14 hour-old infant, the left-to-right shunt was 35% of pulmonary flow. In the other 4 cases, the shunt was either not demonstrable in the LA→pAo curves or too small to be quantitated by the present technic. Accordingly systemic blood flow could not be estimated. Nevertheless, for comparative purposes only the systemic blood flow in these 4 cases and in 5 others were assumed to roughly equal pulmonary flow and were plotted in the scattergram in figure 2 and figure [illegible]. These were, however not included in the derivation of the mean values in Table 1 since, strictly speaking, systemic blood flow should have been less than the corresponding

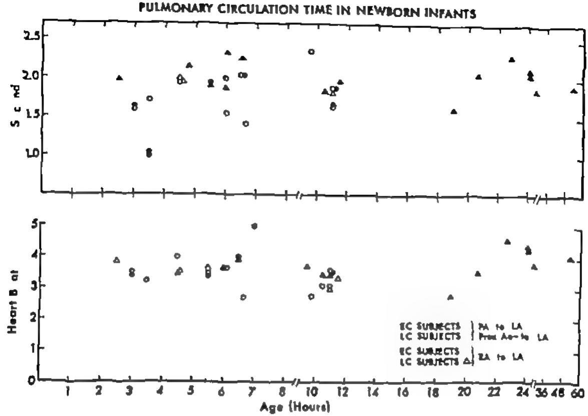

Fig 5 Pulmonary circulation time (in seconds and in heart beats) in the newborn period

pulmonary blood flow since PBF=RVO +L → R shunt) right ventricular output (also equivalent to systemic blood flow in the absence of a L → R shunt at atrial level) systemic vascular resistance, left-to-right shunt, and right-to-left shunt observed in the EC and LC subjects in various age groups The results did not differ significantly in the two groups of subjects.

A left to-right shunt was observed in 34 of 37 infants studied during the first 24 hours. In the majority of these, the shunt represented *less than 50 % of the left ven*tricular output, corresponding to pulmonary systemic flow ratios of less than 0 1 0 (fig 6) The ductal (arteriosus) origin of the shunt was verified by the pAo → LA dye curves except in 6 cases where the confirmatory curves were for technical reasons, not obtained In some cases where the LA → pAo dye curves did not reveal any shunt configuration, the pAo → LA curves demonstrated a small ductal shunt (fig 7) The forward triangle area of the pAo → LA curve was not compared to that of the LA → pAo curve to estimate the relative size of the shunt flow because of the likelihood of incomplete mixing in the proximal aortic chamber and of streaming of the injected dye to the ductal orifice Thus, in *some instances* where pAo → LA curves were repeated at 3- to 6-minute intervals, the curves sometimes varied *significantly* Physiologic changes, e.g transient ductal constriction, could have been contributory factors.

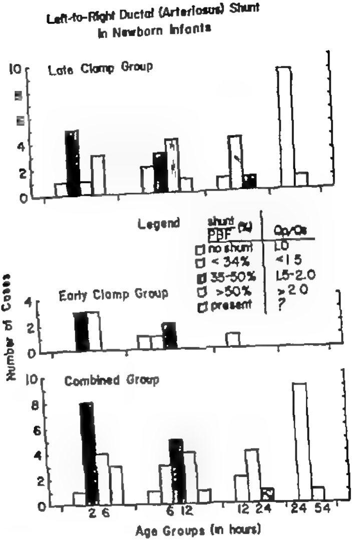

Fig. 6. Relative frequency of left-to-right shunts in the newborn period.

Of the 7 infants aged 12½ to 24 hours, a left-to-right shunt was observed in 5. In one of these, a 14-hour-old infant, the left-to-right shunt was 35 % of pulmonary flow. In the other 4 cases, the shunt was either not demonstrable in the LA→pAo curves or too small to be quantitated by the present technic. Accordingly systemic blood flow could not be estimated. Nevertheless, for comparative purposes only the systemic blood flow in these 4 cases and in 3 others were assumed to roughly equal pulmonary flow and were plotted in the scattergram in figure 2 and figure 9. These were, however, not included in the derivation of the mean values in Table 1 since, strictly speaking, systemic blood flow should have been less than the corresponding

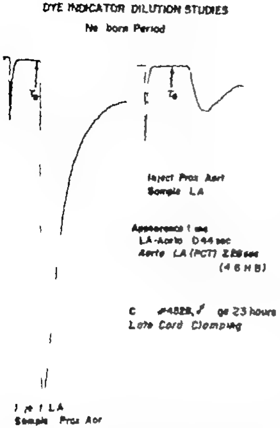

Fig 7 Dye dilution curves of a 23-hour-old LC infant showing no demonstrable shunt pattern in the LA $\rightarrow$ pAo curve but a definite left-to-right ductal shunt in the pAo $\rightarrow$ LA curve

pulmonary flow In 10 infants 25 to 54 hours of age, no shunt pattern was observed in the LA $\rightarrow$ pAo curves. However in a 41 hour-old infant, the pAo $\rightarrow$ LA curves demonstrated a tiny ductal shunt. In 2 other cases, age 25 hours and 29 hours no pAo $\rightarrow$ LA dye curves were obtained to confirm the absence of a ductal left to-right shunt.

A right to-left shunt was noted in only 7 of 45 cases studied and all 7 cases were less than 12 hours of age (fig 9) Verification of the shunt was obtained through repeat injections in the inferior vena cava (or ductus venosus) site which demonstrated a consistent right to-left shunt curve pattern. The size of the shunt was small and varied between 4 % to 7 % of systemic blood flow In 1 case, the shunt was observed only during sampling from the descending aorta and not from the proximal aorta, thus localizing the shunt at the ductus arteriosus level In 3 cases where sampling at the proximal aortic site was not made, shunting across the atrial septum may or may not have been present in addition to that at the ductal level Similarly in 2 cases where the shunt pattern was observed at both aortic sampling sites, shunting could have been at either the atrial level only or at both the atrial and ductal sites.

Pulmonary vascular resistance was calculated in 2 EC and 6 LC subjects and was expressed in resistance units (1 P.R.U = 80 dynes sec. cm^{-5}) This was related to the corresponding systemic resistance in the form of a pulmonary systemic vascular resistance ratio (fig 9) which was felt to be more appropriate for comparative purposes.

Systemic vascular resistance was estimated in 10 EC and in 24 LC infants. The resistance values ranged between 11 5 to 51 3 P.R.U (fig 9) Those of the LC infants were not significantly higher than those of the EC infants. A notable finding was the decline in systemic vascular resistance by the later part of the first day At age 2 to 12 hours, mean systemic resistance of the LC subjects was 30 3 P.R.U $\pm$ 34 S.E. at age 25 to 54 hours, corresponding values were 19 6 P.R.U $\pm$ 32 S.E. ($P<0\ 001$) This change coincided with the reduction or disappearance of the left-to-right shunt and with the increase in systemic blood flow Thus at age 2 to 12 hours, the mean systemic blood flow was 1 96 L/min/M^2 $\pm$ 0 154 S.E., whereas at age 25 to 54 hours it was 3 54 L/min/M^2 $\pm$ 0 238 S.E. ($P<0\ 001$)

Functional patency of the ductus venosus was demonstrated in all of 20 subjects test

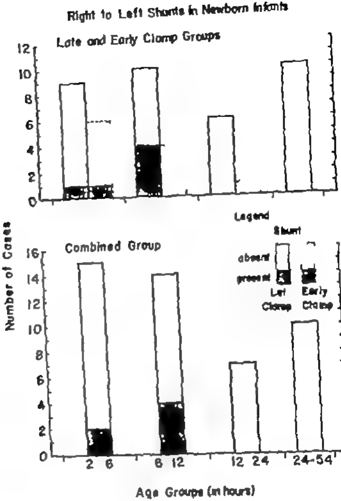

Fig 8 Relative frequency of right-to-left shunts in the newborn period

ed, ranging in age from 3 to 26 hours This was indicated by an umbilical venous injection curve of nearly similar appearance time and configuration to that following *right atrial injection, but with smaller area* since some of the injected dye must have passed directly into the liver by way of the portal circulation. The appearance time of the umbilical venous injection curves was, in general, only slightly longer than that of the right atrial injection curves, the average difference being 0 60 second ± 0.50 S D This slight delay was ascribed to the traversal of the dye across the umbilical vein and constricted ductus venosus. As a rule, the area of the umbilical venous injection *dye curves, relative to that of the right atrial* injection curves, was larger in the very young infants than in the older ones (fig 3) However reproducibility of the curves using varying umbilical venous injection sites was not tested. For this reason, a comparison of the forward triangle area of the umbilical injection curve with that of the

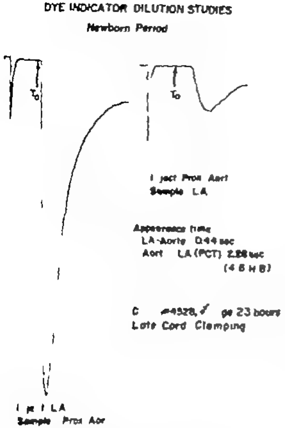

Fig 7 Dye dil tion curves of a 23-hour-old LC infant showing no demonstrable shunt pattern in the LA → pAo curve but a definite left-to-right ductal shunt in the pAo → LA curve

pulmonary flow In 10 infants 25 to 54 hours of age, no shunt pattern was observed in the LA → pAo curves However in a 41 hour-old infant, the pAo → LA curves demonstrated a tiny ductal shunt. In 2 other cases, age 25 hours and 29 hours, no pAo → LA dye curves were obtained to confirm the absence of a ductal left to-right shunt.

A right to-left shunt was noted in only 7 of 45 cases studied, and all 7 cases were less than 12 hours of age (fig 9) Verification of the shunt was obtained through repeat injections in the inferior vena cava (or ductus venosus) site which demonstrated a consistent right to-left shunt curve pattern. The size of the shunt was small and varied between 4 % to 7 % of systemic blood flow In 1 case, the shunt was observed only during sampling from the descending aorta and not from the proximal aorta, thus localizing the shunt at the ductus arteriosus level. In 3 cases where sampling at the proximal aortic site was not made, shunting across the atrial septum may or may not have been present in addition to that at the ductal level. Similarly in 2 cases where the shunt pattern was observed at both aortic sampling sites, shunting could have been at either the atrial level only or at both the atrial and ductal sites.

Pulmonary vascular resistance was calculated in 2 EC and 6 LC subjects and was expressed in resistance units (1 P.R.U = 80 dynes sec. cm⁻⁵) This was related to the corresponding systemic resistance in the form of a pulmonary systemic vascular resistance ratio (fig. 9) which was felt to be more appropriate for comparative purposes.

Systemic vascular resistance was estimated in 10 EC and in 24 LC infants. The resistance values ranged between 11 5 to 51 3 P.R.U (fig 9) Those of the LC infants were not significantly higher than those of the EC infants A notable finding was the decline in systemic vascular resistance by the later part of the first day At age 2 to 12 hours mean systemic resistance of the LC subjects was 30 3 P.R.U ± 2 34 S E. At age 25 to 54 hours, corresponding values were 19 6 P.R.U ± 2 32 S.E. ($P < 0.001$) This change coincided with the reduction or disappearance of the left to-right shunt and with the increase in systemic blood flow Thus at age 2 to 12 hours, the mean systemic blood flow was 1 96 L/min/M² ± 0 154 S.E. whereas at age 25 to 54 hours it was 3 54 L/min/M² ± 0 238 S.E. ($P < 0.001$)

Functional patency of the ductus venosus was demonstrated in all of 20 subjects test

(5 12) These studies were performed chiefly on adults, utilizing peripheral venous or right heart injection and ear lobe or peripheral arterial sampling The proportionality factor (K) of 0 37 and 0 34, established for the forward triangle method in these investigations, represents the ratio of the forward triangle portion to the entire primary curve area, obtained after venous or right heart injection. From 55 left atrial-to-proximal aortic dye curves of 6 LC newborn infants without shunts, we obtained a mean K value of 0.254±0 005 S.E. (11) This factor was accordingly adopted in the present study (see Appendix II)

Implicit in the forward triangle method of cardiac output estimation is the assumption that a constant relationship exists between the forward triangle area of the dye curve and that of the entire primary curve. However, this proportionality may vary slightly in different curves, and this limits the accuracy of this method. In our analysis of the 55 normal LA → pAo curves, the mean difference between the output values obtained by the forward triangle method and the Stewart Hamilton method was 0 051 L/min with a standard deviation of 0 074 (S E ±0.010) Expressed in terms of percent of the Hamilton output value, the mean difference was — 7 6%±11 S.D It is obvious then that isolated instances of gross inaccuracy can occur Nevertheless, for reasons already given, it seems to be the only feasible method of cardiac output estimation presently available in these tiny subjects with left-to-right shunts. This limitation can be minimized by performing repeat dye curves at 2 to 3-minute intervals and deriving the mean output value from 3 or more technically satisfactory curves.

The reproducibility of the dye curves in the present study was comparabl to that found in older subjects by densitometry (6, 7 10 22) or by the Fick method (19 24) It is worth emphasizing that cardiac output values obtained by the present or by any other method are, at best, only an approximation of the actual. This also holds true for other related determinations, namely shunt flow pulmonary vascular resistance, and systemic vascular resistance.

Shunt quantitation by the method used in this study and by others (13) may theoretically speaking, be somewhat over estimated since shunt peak concentration truly represents a summated deflection resulting from the shunt flow and the primary curve exponential decay slope upon which the former is superimposed. The use of an identical K factor of 0.254 for the estimation of the shunt curve area may also be questioned (11) However, Krovetz and Gessner (13) have shown good correlation between the calculated shunts determined by this technic and those determined by oximetry

Our findings of a left-to-right shunt in these term newborn infants during the first day conform with the observations of others based on oximetry data (13 20) However in some instances the shunt may persist longer, as in our 45-hour-old infant with a tiny ductal shunt. Obviously the above observations apply only to normal, full-term infants and not to premature infants, which represent a totally different subject material

Right-to-left shunts have been observed with high frequency during the first hour of life but not by the second hour using the same dye dilution technic presently d scribed (9) From our data, it appears that this shunt, which is small and physiologically insignificant, may still occur at age 2 to 12 hours in about 20% of normal in-

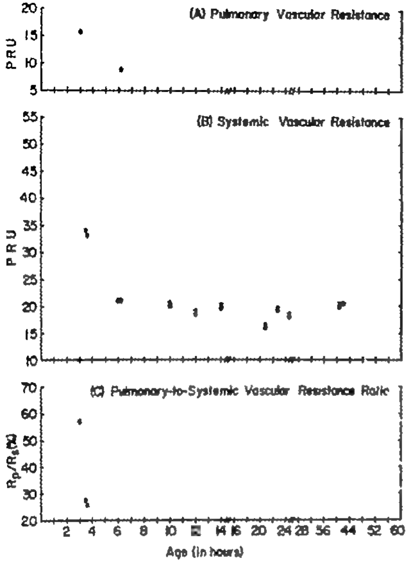

Fig 9 Pulmonary vascular resistance (A) and systemic vascular resistance (B) plotted against age In (C) the two ha e been related in the form of pulmonary systemic resistance ratio The circles with crosses in scattergram (B) refer to the same cases in figure 2 where systemic flow was assumed to equal pulmonary flow

corresponding right atrial injection curve was not made. Theoretically this may have roughly indicated the size of the liver by pass through this route relative to that of the total venous return to the right atrium.

DISCUSSION

Recent studies (9 13) including the present one, demonstrate that the dye dilution technic is applicable for cardiac output and shunt estimation in newborn infants. The method is, however not simply a miniaturized version of that used in older children or adults In the presence of a left to-right shunt, peripheral venous or even right atrial injection is not valid for output estimation since the rapid pulmonary circulation time results in appearance of the shunt flow at about the time of peak concentration with consequent distortion of the primary curve. Separation of the primary curve from the rest of the tracing by logarithmic extrapolation of the disappearance slope is not possible in this situation.

The forward triangle method of cardiac output estimation has been shown to be comparable to the Stewart Hamilton method

of age. A tiny right-to-left shunt was observed only in 7 of 30 infants up to 12 hours of age. Systemic blood flow which was low during the first day increased by the second or third day accompanied by a decline in systemic vascular resistance. The pulmonary and systemic vascular resistance indices were higher than those of normal older children.

No significant differences in the hemodynamic findings of the two groups of infants were observed. Functional patency of the ductus venosus was observed in all 20 subjects tested.

APPENDIX I

Appearance time corrected for catheter delay time (CDT)

(a) $AT = AT - CDT$

where

AT = corrected appearance time
AT = uncorrected appearance time

(b) $CDT = \frac{V}{R} \times 0.6$

where

V = volume of catheter-to-cuvette dead space (ml)
R = pump withdrawal rate (ml/sec)
0.6 = K factor (23)

APPENDIX II

Cardiac output estimation by the forward triangle method

$$CO = \frac{60 \times I}{\frac{1}{2} \times BT \times PC} \times K$$

where

CO = cardiac output (ml/min)
I = dye injected (mg)
BT = build-up time (sec)
PC = peak concentration (mg/L)
K = 0.254 = factor relating forward triangle portion ($\frac{1}{2}\ BT \times PC$) of primary curve to its total area.

fants (fig. 8) Its comparatively higher incidence in the LC subjects than in the EC subjects although not statistically significant, is perhaps related to the high pulmonary artery pressures in the LC infants which tend to remain close to systemic range during the first 7 to 9 hours after birth (3)

A noteworthy finding in this study was the low systemic blood flow during the first day (fig 2 and Table 1) Its increase thereafter coincided with and is presumably related to the disappearance of shunting across the ductus arteriosus. If a cause-and effect relationship truly existed in this circumstance, the possibility of inadequate left ventricular output in the face of the volume overload from the ductal L → R shunt may have to be incriminated

Systemic vascular resistance during the first day is greater than that reported for normal older children (2, 16) this is related to the low systemic flow By the second day systemic arterial pressure and flow are augmented, but the increase in systemic flow is relatively greater indicating a decline in systemic vascular resistance (fig 9) The calculated pulmonary vascular resistances of 8 newborn infants were likewise all above the normal range of 1 to 3 P.R.U observed in normal older children (14, 16) To what extent vasoconstriction contributes to this high resistance state of the newborn pulmonary vascular bed cannot be commented upon in this study Also, it is not possible to state whether pulmonary vascular resistance in the LC subjects differs from that in the EC subjects due to the insufficient number of cases studied (fig 9)

The present data provide some baseline values for comparison with those obtained from abnormal subjects in the same age group The findings also suggest that the circulatory system of the normal term, neonate adapts effectively to varying degrees of placental transfusion and blood volume. When this adaptation is successfully accomplished is not known, but, from our studies at least, it must occur shortly after birth. The high atrial pressures in the LC newborn infants drop to normal levels during the first hour (4) However pulmonary arterial pressures in these subjects remain significantly higher than those in EC infants for several hours (3)

The absence of significant hemodynamic differences between the two groups of subjects in this study does not negate the possibility that these differences may have been demonstrable at age 1 or 2 hours.

The significance of transient patency of the ductus venosus after birth is not known. It is conceivable that the magnitude of the flow through this structure (which represents a liver by pass) could significantly influence liver function in the human newborn.

SUMMARY

Dye dilution studies by the double catheter technic were performed on 47 normal, term, newborn infants 2½ to 54 hours of age. According to the time of cord clamping, the subjects were divided into two groups (1) early clamp group — 11 infants and, (2) late clamp group — 36 infants

Cardiac output and left to-right shunt were calculated from the LA → pAo curves and, in eight instances, from the PA → LA curves by the forward triangle method. A left-to-right shunt across the ductus arteriosus was generally observed during the first day although at age 1 to 24 hours this shunt was already very small It was noted in only 1 of 10 infants over 24 hours

of age. A tiny right-to-left shunt was observed only in 7 of 30 infants up to 12 hours of age. Systemic blood flow which was low during the first day increased by the second or third day accompanied by a decline in systemic vascular resistance. The pulmonary and systemic vascular resistance indices were higher than those of normal older children.

No significant differences in the hemodynamic findings of the two groups of infants were observed. Functional patency of the ductus venosus was observed in all 20 subjects tested.

Among the various potential hazards during the adaptation of the newborn infant to extrauterine life, systemic circulatory hypotension may be mentioned as a possible cause for defective institution of pulmonary function. The background for this reasoning, with respect to the central circulatory pattern is that systemic hypotension may jeopardize the pulmonary perfusion by reducing the aorto-pulmonary pressure gradient and thereby diminishing or possibly reversing the left right shunt through the patent ductus arteriosus. As this shunt may be assumed to promote adequate pulmonary perfusion, particularly during the establishment of pulmonary function in the immediate neonatal period, its reduction or absence might result in impairment of the ventilation/perfusion ratio of the lung and delayed closing of the foramen ovale. It has also been implied that impaired pulmonary perfusion may adversely affect the mechanical characteristics of the expanding neonatal lung and thereby the work of breathing (19).

In the search for possible pathogenetic links between the perinatal circulatory adaptation and respiratory dysfunction in the newborn infant, the capacity of the newborn to maintain systemic blood pressure homeostasis has accordingly been investigated. Experimental procedures have included studies of blood pressure control during body tilting (14, 2) and during acutely induced hypovolemia (19, 3). It has been concluded from the latter studies that changes of the blood volume in the range 10—25 per cent of predicted total blood volume (PTBV) are capable of inducing considerable blood pressure drop on the arterial as well as on the venous side of the circulation. These findings were interpreted as indicating that the newborn's capacity to adapt its vascular volume to the available blood volume is less well developed than later in life.

Earlier studies of blood pressure homeostasis during blood volume alterations lacked information regarding the effect on cardiac output, central shunting and resistance. However, simultaneous evaluation of the roentgenological heart size and appearance of the pulmonary vessels in chest films indicated a pronounced effect on the stroke and minute volume of the heart as well as the vascular volume of the lungs.

The present investigation was undertaken in order to study with more sophisticated quantitative methods the effect of moderate hypovolemia on the newborn infant's central circulatory pattern with special regard to cardiac output, pulmonary circulation and central shunts.

MATERIAL AND METHODS

Six normal fullterm infants, ranging in age from 7 to 28 hours and in weight from 3.3 to 3.8 kg constitute the subject material for the present study. All of the babies were products of normal gestations and their perinatal and postnatal course was judged uneventful. They were all vertex deliveries and the umbilical cord was ligated when pulsations had ceased, usually not earlier than two minutes after delivery of the trunk. The babies were usually investigated,

(18) Immediately after withdrawal of the blood a new set of recordings was made and a further blood volume depletion of the same magnitude was performed. During this second stage of hypovolemia, corresponding to a total depletion of 15 per cent of PTBV new recordings of flow and pressures were made. The blood was thereafter re-infused and a set of final tracings recorded. Each stage lasted approximately five minutes, and no attempts were made to study the circulatory effect of prolonged hypovolemia.

In order to avoid changes of catheter position between tracings both catheters were tightly secured to the umbilical stump during the whole procedure. The body temperature of the babies usually did not change significantly and was maintained whenever necessary by heat radiation. Room temperature was in the range 25—27°C. Statistical analysis of data was performed according to standard methods on an IBM 1130 Data Processor.

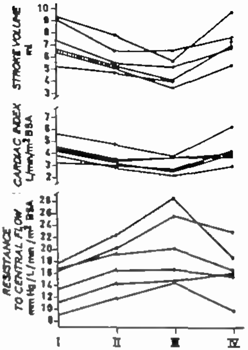

Fig. 1. Stroke volume, blood flow and resistance to blood flow as calculated in the ascending portion of the aorta. Roman symbols I—IV stand for control observation, depletion with 7.5 per cent of PTBV, depletion with 15 per cent of PTBV and observation after restitution of blood volume respectively.

RESULTS

The circulatory consequences of hypovolemia are listed in Table I and are graphically reproduced in Fig. 1. There is in all instances a statistically significant reduction of the left ventricular output following PTBV depletion of 7.5 per cent. This decrease is further accentuated in five of the cases when the depletion is doubled, but remains almost unchanged in the sixth case.

The average reduction in cardiac output during the initial depletion amounts to 191 ml/min, which corresponds to 20 per cent of the initial recording. The average additional reduction during the second stage of depletion is 107 ml/min, which makes a total of 298 ml/min or 33 per cent of the baseline value. The restitution of blood increased the cardiac output in 2 cases slightly above initial levels, in 2 to a level slightly below the initial observation and in the remaining 2 cases the cardiac output returned to a level considerably lower than the initial observation.

The heart rate was only slightly affected during the hypovolemic state and the drop in left ventricular output was therefore almost entirely due to reduction of the stroke volume. Stroke volume dropped 24 per cent during the first stage of hypovolemia and to a total of 40 per cent during the second stage. Aortic mean pressure was

with exception of the youngest ones in whom feeding had not been initiated 1—2 hours after a meal and were therefore usually sleeping during the entire procedure Hemoglobin as well as hematocrit readings were within normal limits for the age.

The procedure and technique used to assess the cardiac output has recently been described in detail (9) and shall only be briefly outlined. After appropriate sterile preparation of the umbilical stump an infant feeding tube size F 5 was advanced through the umbilical vein and the ductus venosus to the right and subsequently to the left atrium. The left atrial location of the catheter was checked by monitoring the pressure curve and, if considered neccessary by determination of the oxygen saturation of the blood An identical feeding tube was subsequently advanced through one of the umbilical arteries and placed above the ductus arteriosus in the ascending aorta. The location of this catheter was confirmed in two instances by pull back from the left ventricle and in the remaining four cases by the identification of a left right ductal shunt following dye injection into the aorta and sampling from the left atrium Both catheters were connected to pressure transducers and pressure recordings from the aorta and atria were made The pressure signals were recorded together with an ECG signal on a direct writing multichannel instrument To keep the catheters free of clots they were occasionally flushed with 1—2 ml physiological saline containing 0 2 per cent heparin.

Dye dilution studies In order to assess the left ventricular output 0 2 mg Cardiogreen® was injected into the left atrium (LA) and blood was sampled from the ascending aorta (Ao) by continuous withdrawal at a rate of 15 ml/min through a densitometer cuvette The dilution curve was recorded on a writer with linear output, a chart width of 25 cm and a response time of 0 9 second for 90 % of the total deflection. The attenuator of the recorder was set to give a 15—20 cm deflection for the peak concentration of the primary curve Due to sterile preparation of the cuvette the blood could be returned to the infant after every tracing Calibration of the instrument was made according to a technique earlier described (9) using the infants own blood. Quantitative evaluation of the dilution curve was made by use of the forward triangle method (10) revised in this laboratory for application to the newborn infant (9) Left ventricular minute output was computed as the mean of at least three technically acceptable dye dilution curves Dye injections were made within the shortest possible interval, usually not exceeding two minutes. The heart rate was obtained by continuous ECG recording during the injection and sampling. Systemic blood pressure was recorded immediately before and after each tracing Resistance to blood flow in the ascending aorta was estimated from the left ventricular minute output and the aortic mean pressure and expressed in central resistance units (CRU) as mm Hg/1/min/m^2 BSA. The relative magnitude of the left right shunt through the ductus arteriosus could usually be assessed from the recirculation deflection on the descending part of the LA Ao primary dye curve (12)

After initial basal determination of the parameters under investigation hypovolemia was induced step-wise in the following manner An amount corresponding to 7 5 per cent of the predicted blood volume was withdrawn into a heparinized syringe The blood volume of the infant was predicted from the age and weight of the infant under study according to available literature data

(18) Immediately after withdrawal of the blood a new set of recordings was made and a further blood volume depletion of the same magnitude was performed. During this second stage of hypovolemia, corresponding to a total depletion of 15 per cent of PTBV new recordings of flow and pressures were made. The blood was thereafter re-infused and a set of final tracings recorded. Each stage lasted approximately five minutes, and no attempts were made to study the circulatory effect of prolonged hypovolemia.

In order to avoid changes of catheter position between tracings both catheters were tightly secured [redacted] the umbilical stump during the whole procedure. The body temperature of the babies usually did not change significantly and was maintained whenever necessary by heat radiation. Room temperature was in the range 25—27°C. Statistical analysis of data was performed according [redacted] standard methods on an IBM 1130 Data Processor

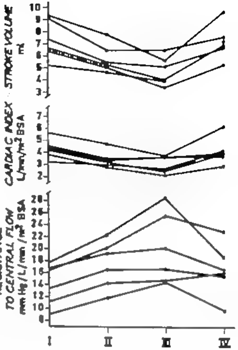

Fig. 1 Stroke volume, blood flow and resistance to blood flow as calculated in the ascending portion of the aorta. Roman symbols I—IV stand for control observation, depletion with 5 per cent of PTBV, depletion with 15 per cent of PTBV and observation after restitution of blood volume respectively.

RESULTS

The circulatory consequences of hypovolemia are listed in Table I and are graphically reproduced in Fig. 1. There is in all instances a statistically significant reduction of the left ventricular output following PTBV depletion of 7.5 per cent. This decrease [redacted] further accentuated in five of the cases when the depletion is doubled, but remains almost unchanged in the sixth case.

The average reduction in cardiac output during the initial depletion amounts to 191 ml/min, which corresponds [redacted] 20 per cent of the initial recording. The average additional reduction during the second stage of depletion [redacted] 107 ml/min, which makes a total of 298 ml/min or 33 per cent of the baseline value. The restitution of blood increased the cardiac output in 2 cases slightly above initial levels, in 2 to a level slightly below the initial observation and in the remaining 2 cases the cardiac output returned to a level considerably lower than the initial observation.

The heart rate was only slightly affected during the hypovolemic state and the drop in left ventricular output was therefore almost entirely due to reduction of the stroke volume. Stroke volume dropped 24 per cent during the first stage of hypovolemia and to a total of 40 per cent during the second stage. Aortic mean pressure was

with exception of the youngest ones in whom feeding had not been initiated 1—2 hours after a meal and were therefore usually sleeping during the entire procedure Hemoglobin as well as hematocrit readings were within normal limits for the age

The procedure and technique used to assess the cardiac output has recently been described in detail (9) and shall only be briefly outlined After appropriate sterile preparation of the umbilical stump an infant feeding tube size F 5 was advanced through the umbilical vein and the ductus venosus to the right and subsequently to the left atrium. The left atrial location of the catheter was checked by monitoring the pressure curve and if considered necessary by determination of the oxygen saturation of the blood An identical feeding tube was subsequently advanced through one of the umbilical arteries and placed above the ductus arteriosus in the ascending aorta. The location of this catheter was confirmed in two instances by pull-back from the left ventricle and in the remaining four cases by the identification of a left right ductal shunt following dye injection into the aorta and sampling from the left atrium. Both catheters were connected to pressure transducers and pressure recordings from the aorta and atria were made The pressure signals were recorded together with an ECG signal on a direct writing multichannel instrument. To keep the catheters free of clots they were occasionally flushed with 1—2 ml physiological saline containing 0 2 per cent heparin

Dye dilution studies In order to assess the left ventricular output 0 2 mg Cardiogreen® was injected into the left atrium (LA) and blood was sampled from the ascending aorta (Ao) by continuous withdrawal at a rate of 15 ml/min through a densitometer cuvette. The dilution curve was recorded on a writer with linear output, a chart width of 25 cm and a response time of 0 9 second for 90 % of the total deflection. The attenuator of the recorder was set to give a 15—20 cm deflection for the peak concentration of the primary curve Due to sterile preparation of the cuvette the blood could be returned to the infant after every tracing Calibration of the instrument was made according to a technique earlier described (9) using the infants own blood. Quantitative evaluation of the dilution curve was made by use of the forward triangle method (10) revised in this laboratory for application to the newborn infant (9) Left ventricular minute output was computed as the mean of at least three technically acceptable dye dilution curves. Dye injections were made within the shortest possible interval, usually not exceeding two minutes. The heart rate was obtained by continuous ECG recording during the injection and sampling Systemic blood pressure was recorded immediately before and after each tracing Resistance to blood flow in the ascending aorta was estimated from the left ventricular minute output and the aortic mean pressure and expressed in central resistance units (CRU) as mm Hg/l/min/m^2 BSA The relative magnitude of the left right shunt through the ductus arteriosus could usually be assessed from the recirculation deflection on the descending part of the LA Ao primary dye curve (12)

After initial basal determination of the parameters under investigation hypovolemia was induced step-wise in the following manner An amount corresponding to 7 5 per cent of the predicted blood volume was withdrawn into a heparinized syringe The blood volume of the infant was predicted from the age and weight of the infant under study according to available literature data

of hypovolemia the central resistance increased some 40 per cent and during the second stage an average increase of 58 per cent above the initial observation was recorded.

A functional patency of the ductus arteriosus was demonstrated in all cases and was also verified by interchanging injection and sampling sites. Right atrial injection prior to hypovolemia demonstrated a small right left shunt through the foramen ovale in only one of the cases. Pulmonary circulation time, measured as the difference in appearance time between right and left atrial injections and sampling in the ascending aorta, varied between 1.6 and 2.3 seconds. Changes in the pulmonary transit time during hypovolemia could not be studied as right-sided injections were not performed during depletion. The left-right shunt through the ductus arteriosus was small or insignificant in 3 instances on the initial observation, whereas in the remaining 3 cases there was a 40—55 % per cent shunt present. During hypovolemia no consistent change in the size of these shunts could be traced, and the ratio peak primary dye curve deflection to peak shunt deflection remained unchanged throughout. It is noteworthy that in one infant with insignificant ductal shunt on initial as well as hypovolemic dye curves, a 45 per cent left-right ductal shunt was present after restitution of blood volume.

DISCUSSION

Data from the literature pertaining to the cardiovascular response to hypovolemia are somewhat conflicting. Warren et al. (21) stat that bleeding normal man 5—15 per cent of his total blood volume does not significantly change systemic mean pressure, peripheral resistance or cardiac output. Contrary to this statement others have reported pronounced reduction of stroke volume and minute volume but well maintained systemic pressures during moderate hypovolemia (13, 17). Whereas it has been suggested that adult man is capable of systemic blood pressure homeostasis in the presence of acute bleeding not exceeding 30 per cent of the estimated total blood volume (1) a marked systemic hypotension has been reported after considerably less pronounced blood volume depletions in the newborn infant (19). It would seem appropriate to relate the hypovolemic response not only to the volume depleted but also to the composition of the subject material investigated, time factors etc.

Ralston et al. (17) performed dye dilution studies in adult man during blood volume depletion of the same relative magnitude as those in the present investigation, and report an average decrease in cardiac output of 15 per cent with a stroke volume reduction of 12 per cent. Systemic pressures remained more or less unchanged with a 10 per cent average increase of the vascular resistance. With a comparable degree of hypovolemia it is evident that, whereas systemic perfusion pressure is equally well maintained, cardiac output and systemic vascular resistance are considerably more affected in the newborn infant. There are at least two valid explanations for this difference. One is related to the presence of a ductal shunt in most of the infants studied, and the other to a more pronounced effect on the venous filling of the heart in the newborn infant.

Since our measurements of cardiac output refer to the actual left ventricular output, a change in magnitude of functioning ductal shunt must influence the calculated minute output of the left ventricle. Reduc

only moderately affected both during the first and second stage, and as a rule there was an overshoot of the aortic pressures after blood volume restitution. Left atrial mean pressure decreased considerably during the smaller depletion when an average pressure drop of 2 5 mm Hg mean pressure was recorded. There was as a rule no further decrease in this pressure during subsequent depletion A slight overshoot was also noted in the left atrial pressure during the final recording

The resistance to blood flow in the ascending aorta which, in the presence of an open ductus arteriosus reflects the combined resistance of the systemic and pulmonary circulation increased considerably during hypovolemia. *During the first stage*

of hypovolemia the central resistance increased some 40 per cent and during the second stage an average increase of 58 per cent above the initial observation was recorded.

A functional patency of the ductus arteriosus was demonstrated in all cases and was also verified by interchanging injection and sampling sites. Right atrial injection prior to hypovolemia demonstrated a small right-left shunt through the foramen ovale in only one of the cases. Pulmonary circulation time, measured as the difference in appearance time between right and left atrial injections and sampling in the ascending aorta, varied between 1.6 and 2.3 seconds. It is noteworthy that in one infant with insignificant ductal shunt on initial as well as hypovolemic dye curves, a 45 per cent left-right ductal shunt was present after restitution of blood volume.

DISCUSSION

Data from the literature pertaining to the cardiovascular response to hypovolemia are somewhat conflicting. Warren et al. (21) state that bleeding normal man 5—15 per cent of his total blood volume does not significantly change systemic mean pressure, peripheral resistance or cardiac output. Contrary to this statement others have reported pronounced reduction of stroke volume and minute volume but well maintained systemic pressures during moderate hypovolemia (13, 17). Whereas it has been suggested that adult man is capable of systemic blood pressure homeostasis in the presence of acute bleeding not exceeding 30 per cent of the estimated total blood volume (1), a marked systemic hypotension has been reported after considerably less pronounced blood volume depletions in the newborn infant (19). It would seem appropriate to relate the hypovolemic response not only to the volume depleted but also to the composition of the subject material investigated, time factors etc.

Ralston et al. (17) performed dye dilution studies in adult man during blood volume depletion of the same relative magnitude as those in the present investigation, and report an average decrease in cardiac output of 13 per cent with a stroke volume reduction of 12 per cent. Systemic pressures remained more or less unchanged with a 10 per cent average increase of the vascular resistance. With a comparable degree of hypovolemia it is evident that, whereas systemic perfusion pressure is equally well maintained, cardiac output and systemic vascular resistance are considerably more affected in the newborn infant. There are at least two valid explanations for this difference. One is related to the presence of a ductal shunt in most of the infants studied, and the other to a more pronounced effect on the venous filling of the heart in the newborn infant.

Since our measurements of cardiac output refer to the actual left ventricular output, a change in magnitude of functioning ductal shunt must influence the calculated minute output of the left ventricle. Reduc

tion of the ductal shunt may be occasioned by a diminished pressure gradient between aorta and the pulmonary artery or by a con striction of the ductal lumen. Dye dilution patterns during the hypovolemic stages however did not indicate any significant change in the relative magnitude of the duc tal shunt If it is assumed that the intrinsic pumping capacity of the myocardium remains unchanged during hypovolemia, the reduced left ventricular output must be related to a decreased filling of the right heart, and this effect is evidently more pronounced in neonates than in normal adult man.

Maintainance of venous return during hemorrhage is achieved chiefly by constric tion of the post-capillary or capacitance vessels resulting in a centripetal redistribu tion of blood with mobilization of pooled venous blood The constrictive capacity of the capacitance vessels or the actual tone of these vascular compartments will consequently be the controlling factor in the maintainance of venous return to the right heart. In animal experiments it has been shown that the mean circulatory pressure (the pressure in the circulatory system in the absence of flow) which is affected by the tonus of the capacitance vessels, is also related to venous return to the heart and drops considerably during hemorrhage (7 8)

The possibility that the effect on the mean circulatory pressure is more pronounc ed in the newborn infant is in agreement with the earlier reported finding (19) that the newborn s capacity to adapt its vascular volume to actual total blood volume is less well developed than later in life The impressive response of the systemic vascular resistance recorded in the present investiga tion should be regarded as indicating that the infant is struggling by means of its impressive vaso-motor control (3 20) to establish blood pressure homeostasis in the presence of a markedly reduced cardiac out put.

Although in the present investigation we have not studied changes occuring in the pulmonary circulation, our data allow some conclusions to be drawn In the absence of a right left shunt at the atrial level the pulmonary blood flow must be considered identical with the left ventricular output in these infants As no significant shunt was recorded at this level prior to the hypovolemic situation, the reduction of the left ventricular output must have been paralelled or even exceeded by that in the pulmonary circulation. If it is accepted, with due respect to our limitations in assessing these para meters, that ductal resistance as well as the relative magnitude of ductal blood flow did not significantly change during hypovolemia, the aorto-pulmonary pressure gra dient must have been well maintained. This would imply that the resistance of the pul monary vascular bed has increased concomitantly with the reduction of the pul monary blood flow

Our knowledge regarding the control of pulmonary vascular resistance in the new born is mostly derived from studies in ani mals and pertains particularly to the late fetal and immediate neonatal period We know from these investigations that the pul monary resistance in the perinatal period is subject to variations in response to a number of stimuli Whereas vaso-dilatation is caused by increasing the oxygen tension in the alveoli or decreasing the carbon dioxide tension (11) merely by the ventilation of the collapsed lung (4) or by the administra tion of acetylcholine (14) vasoconstriction is reported to occur during the opposite

condition (25 11) It is evident that at least with respect to the response to catecholamines the late fetal pulmonary vessels of the lamb react much the same as does the systemic circulation (2) Although to our knowledge no study has been reported with respect to the excretion and effect of catecholamines during hypovolemia at this age, it is tempting to assume that the increase in vascular tone of the systemic and pulmonary circulation is mediated through the action of adrenergic substances.

Whereas the effect of the pulmonary circulation of hypervolemia is well studied, reports on the effect of hypovolemia are scarce. DeFreitas et al. (6) demonstrated that during pooling of blood in the four extremities of normal man cardiac output decreased an average of 16 per cent with concomitant rises in pulmonary vascular resistance of 11 per cent and in systemic resistance of 18 per cent From these studies it would appear that in adult man hypovolemia causes a more pronounced hypotension in the pulmonary circulation. It is probably not feasible from the present studies to say whether the capacity of the pulmonary circulation to increase vascular resistance is equally or better developed in the newborn infant.

In an earlier investigation of the circulatory response to hypovolemia in the newborn infant we concluded that whereas bleeding approximately 10 per cent of the total blood volume does not seem to affect systemic blood pressure markedly depletion of amounts corresponding to 20—25 per cent of the blood volume resulted in a fall in both systemic and pulmonary blood pressures From indirect observations it was suggested that hypovolemia in the newborn was characterized by a diminished stroke and minute volume Although the earlier investigation is not quite comparable with respect to subject material, the results in the present investigation seem to be in good agreement with the earlier observations. They suggest that the normal infant is usually capable of maintaining systemic blood pressure if blood loss does not exceed 10—15 per cent of PTBV It is very likely that the greater blood volume depletion of the earlier study exceeded the capacity of vasomotor control. From experiments in adult man this is known to occur when bleeding exceeds some 30 per cent of the total blood volume (1) It would seem that this limit is lower in the newborn infant, due mainly to the more pronounced effect on venous return to the heart.

The question of possible adverse effects of hypovolemia on respiratory function during the perinatal period may relate to the effects of lowered pulmonary perfusion as well as decreased pulmonary blood volume and pulmonary arterial pressure on the mechanical behaviour of the lungs. From the present investigation it may be concluded that moderate hypovolemia does not interfere with the central shunt pattern, and that systemic circulation is not being maintained at the expense of pulmonary perfusion. The fact remains, however that pulmonary blood flow is markedly reduced during hypovolemia, and may impair the ventilatory function of the lungs. It has recently been pointed out (16) that a newborn infant deprived of the placental transfusion demonstrates typical signs of hypovolemia, and has a significantly higher clearance of carbon dioxide and a higher oxygen saturation than do infants who have received this transfusion. It is tempting to interpret this as a result of a change in ventilation/perfusion relationships of the lungs. The finding that early-clamped infants exhibit a sig

tion of the ductal shunt may be occasioned by a diminished pressure gradient between aorta and the pulmonary artery or by a constriction of the ductal lumen. Dye dilution patterns during the hypovolemic stages, however did not indicate any significant change in the relative magnitude of the ductal shunt. If it is assumed that the intrinsic pumping capacity of the myocardium remains unchanged during hypovolemia, the reduced left ventricular output must be related to a decreased filling of the right heart, and this effect is evidently more pronounced in neonates than in normal adult man.

Maintainance of venous return during hemorrhage is achieved chiefly by constriction of the post-capillary or capacitance vessels resulting in a centripetal redistribution of blood with mobilization of pooled venous blood. The constrictive capacity of the capacitance vessels or the actual tone of these vascular compartments will consequently be the controlling factor in the maintainance of venous return to the right heart. In animal experiments it has been shown that the mean circulatory pressure (the pressure in the circulatory system in the absence of flow) which is affected by the tonus of the capacitance vessels, is also related to venous return to the heart and drops considerably during hemorrhage (7 8).

The possibility that the effect on the mean circulatory pressure is more pronounced in the newborn infant is in agreement with the earlier reported finding (19) that the newborn's capacity to adapt its vascular volume to actual total blood volume is less well developed than later in life. The impressive response of the systemic vascular resistance recorded in the present investigation should be regarded as indicating that the infant is struggling by means of its impressive vaso-motor control (3 20) to establish blood pressure homeostasis in the presence of a markedly reduced cardiac output.

Although in the present investigation we have not studied changes occuring in the pulmonary circulation, our data allow some conclusions to be drawn. In the absence of a right-left shunt at the atrial level the pulmonary blood flow must be considered identical with the left ventricular output in these infants. As no significant shunt was recorded at this level prior to the hypovolemic situation, the reduction of the left ventricular output must have been paralelled or even exceeded by that in the pulmonary circulation. If it is accepted, with due respect to our limitations in assessing these parameters, that ductal resistance as well as the relative magnitude of ductal blood flow did not significantly change during hypovolemia, the aorto-pulmonary pressure gradient must have been well maintained. This would imply that the resistance of the pulmonary vascular bed has increased concomitantly with the reduction of the pulmonary blood flow.

Our knowledge regarding the control of pulmonary vascular resistance in the newborn is mostly derived from studies in animals and pertains particularly to the late fetal and immediate neonatal period. We know from these investigations that the pulmonary resistance in the perinatal period is subject to variations in response to a number of stimuli. Whereas vaso-dilatation is caused by increasing the oxygen tension in the alveoli or decreasing the carbon dioxide tension (11) merely by the ventilation of the collapsed lung (4) or by the administration of acetylcholine (14) vasoconstriction is reported to occur during the opposite

coordation (23, 11). It is evident that at least with respect to the response to catecholamines the late fetal pulmonary vessels of the lamb react much the same as does the systemic circulation (2). Although to our knowledge no study has been reported with respect to the excretion and effect of catecholamines during hypovolemia at this age, it is tempting to assume that the increase in vascular tone of the systemic and pulmonary circulation is mediated through the action of adrenergic substances.

Whereas the effect of the pulmonary circulation of hypervolemia is well studied, reports on the effect of hypovolemia are scarce. DeFreitas et al. (6) demonstrated that during pooling of blood in the four extremities of normal man cardiac output decreased an average of 16 per cent with concomitant rises in pulmonary vascular resistance of 11 per cent and in systemic resistance of 18 per cent. From these studies it would appear that in adult man hypovolemia causes a more pronounced hypotension in the pulmonary circulation. It is probably not feasible from the present studies to say whether the capacity of the pulmonary circulation to increase vascular resistance is equally or better developed in the newborn infant.

In an earlier investigation of the circulatory response to hypovolemia in the newborn infant we concluded that whereas bleeding approximately 10 per cent of the total blood volume does not seem to affect systemic blood pressure markedly, depletion of amounts corresponding to 20—25 per cent of the blood volume resulted in a fall in both systemic and pulmonary blood pressures. From indirect observations it was suggested that hypovolemia in the newborn was characterized by a diminished stroke and minute volume. Although the earlier investigation is not quite comparable with respect to subject material, the results in the present investigation seem to be in good agreement with the earlier observations. They suggest that the normal infant is usually capable of maintaining systemic blood pressure if blood loss does not exceed 10—15 per cent of PTBV. It is very likely that the greater blood volume depletion of the earlier study exceeded the capacity of vasomotor control. From experiments in adult man this is known to occur when bleeding exceeds some 30 per cent of the total blood volume (1). It would seem that this limit is lower in the newborn infant, due mainly to the more pronounced effect on venous return to the heart.

The question of possible adverse effects of hypovolemia on respiratory function during the perinatal period may relate to the effects of lowered pulmonary perfusion as well as decreased pulmonary blood volume and pulmonary arterial pressure on the mechanical behaviour of the lungs. From the present investigation it may be concluded that moderate hypovolemia does not interfere with the central shunt pattern, and that systemic circulation is not being maintained at the expense of pulmonary perfusion. The fact remains, however, that pulmonary blood flow is markedly reduced during hypovolemia, and may impair the ventilatory function of the lungs. It has recently been pointed out (16) that a newborn infant deprived of the placental transfusion demonstrates typical signs of hypovolemia, and has a significantly higher clearance of carbon dioxide and higher oxygen saturation than do infants who have received this transfusion. It is tempting to interpret this as a result of a change in ventilation/perfusion relationships of the lungs. The finding that early-clamped infants exhibit a sig-

nificantly larger V_{FRC} (15) may be in line with this assumption. We have no means of determining from the present investigation whether a similar beneficial effect is effected during a considerably smaller depletion of blood volume. Investigations to elucidate this aspect are currently being undertaken.

A reduction of central blood volume may conceivably alter the mechanical characteristics of the lungs. Although recent studies of acute bleeding in normal man suggest that pulmonary blood volume is kept fairly constant (6 24) intrathoracic blood volume, including the large vessels and the heart which are known to reduce their volume during hypovolemia (19) may produce changes in respiratory mechanics It has, indeed been shown (15) that low initial blood volume in the newborn infant is associated with high V_{FRC} and pulmonary compliance, an effect that would be expected to reduce the work of breathing.

It may probably be stated that after respiration is established moderate hypovolemia does not have any adverse effect on this respiration. Whether there may be adverse effects during the initiation of breathing must be studied in the delivery room. Investigations along these lines are in progress as a logical continuation of the present investigation

SUMMARY

6 newborn infants 7—28 hours old were investigated with respect to changes in cardiac output, central circulatory pattern and vascular resistance after blood volume depletions of 7 5 per cent and 15 per cent of predicted total blood volume. Concomitant with a marked drop in left ventricular output and stroke volume, resistance to flow in the ascending aorta increased considerably but systemic blood pressure was only moderately affected Hypovolemia caused no demonstrable change in the size of the ductal shunt which was demonstrated in 5 of the cases. The recorded drop in stroke and minute volume is considerably greater than that occurring after corresponding blood volume depletion in the adult. The background for this difference is discussed. It is suggested that hypovolemia exerts a more pronounced effect on the venous return to the heart due to less efficient control of the capacitance vessels in the newborn.

nificantly larger V_{TRO} (15) may be in line with this assumption We have no means of determining from the present investigation whether a similar beneficial effect is effected during a considerably smaller depletion of blood volume. Investigations to elucidate this aspect are currently being undertaken.

A reduction of central blood volume may conceivably alter the mechanical characteristics of the lungs. Although recent studies of acute bleeding in normal man suggest that pulmonary blood volume is kept fairly constant (6, 24) intrathoracic blood volume, including the large vessels and the heart which are known to reduce their volume during hypovolemia (19) may produce changes in respiratory mechanics. It has, indeed, been shown (15) that low initial blood volume in the newborn infant is associated with high V_{TRO} and pulmonary compliance, an effect that would be expected to reduce the work of breathing

It may probably be stated that after respiration is established moderate hypovolemia does not have any adverse effect on this respiration. Whether there may be adverse effects during the initiation of breathing must be studied in the delivery room. Investigations along these lines are in progress as a logical continuation of the present investigation.

SUMMARY

6 newborn infants 7—28 hours old were investigated with respect to changes in cardiac output, central circulatory pattern and vascular resistance after blood volume depletions of 7 5 per cent and 15 per cent of predicted total blood volume. Concomitant with a marked drop in left ventricular output and stroke volume, resistance to flow in the ascending aorta increased considerably but systemic blood pressure was only moderately affected Hypovolemia caused no demonstrable change in the size of the *ductal shunt which* was *demonstrated in 5* of the cases. The recorded drop in stroke and minute volume is considerably greater than that occurring after corresponding blood volume depletion in the adult. The background for this difference is discussed. It is suggested that hypovolemia exerts a more pronounced effect on the venous return to the heart due to less efficient control of the capacitance vessels in the newborn.

QUANTITATIVE STUDIES OF THE HUMAN NEONATAL CIRCULATION

IV OBSERVATIONS ON THE NEWBORN INFANT'S PERIPHERAL CIRCULATION AND PLASMA EXPANSION DURING MODERATE HYPOVOLEMIA

In a foregoing communication (29) it was pointed out, that whereas the left ventricular output decreased considerably during a moderate reduction of the total blood volume in the newborn infant, systemic blood pressure was well maintained as a consequence of increased vascular resistance. The efficiency with which this was achieved indicates a very capable vasomotor control in the newborn in response to hypovolemia. It also prompts a further appreciation of its role in the regulation of systemic blood pressure.

Whereas the technical set-up and procedures for the evaluation of the central circulatory pattern usually are complicated and require access to intravascular compartments, methods for the study of peripheral blood flow are less cumbersome. The most commonly used technique for the study of peripheral circulation is that of venous occlusion plethysmography where the arterial inflow to a limb or parts of it is measured as volume increase of the segment after occlusion of the venous outflow. This technique has been widely used and values compare well with those obtained by more direct flow metering devices (13). Since the plethysmographic method measures volume changes in a section of the limb defined by the plethysmograph, the flow figures are given in terms of blood flow per unit time per unit tissue volume (ml/min/100 ml).

Occlusion plethysmography has been adapted for use in newborn infants, and the peripheral circulation has been analysed both in health and disease and during various experimental conditions. It has been demonstrated that blood flow in the extremities is greater and resistance to flow less in the newborn than in adult man (6). It has also been pointed out that this difference is considerably more pronounced in the premature infant (6, 22). Recent studies indicate that the newborn asphyxiated infant, as well as the normal infant exposed to hypoxic environment, increases peripheral resistance considerably (6) and it has also been shown that resting blood flow may increase drastically during reactive hyperemia of the limb (5).

That portion of peripheral blood flow which supplies the skin has attracted special attention due to its heat regulating properties. Whereas an absolute quantitation of this flow requires special methods, changes occurring in the cutaneous circulation may be traced by monitoring the skin temperature (11, 7). The vascular control of cutaneous circulation in the newborn infant has been thoroughly investigated (1) and it is today well documented that the newborn responds to temperature stimuli with great variations in skin blood flow.

It is evident from the cited reports that the vascular tone of the peripheral circulation is already actively participating in circulatory and metabolic control during the first hours of life. The present investigation was undertaken to study the circulatory changes induced in the calf of the newborn infant by moderate blood volume reduction. It is the purpose of the study to evaluate the peripheral circulation's function in controlling blood pressure in the neonate.

The present investigation was undertaken to study the circulatory changes induced in the calf of the newborn infant by moderate blood volume reduction. It is the purpose of the study to evaluate the peripheral circulation's function in controlling blood pressure in the neonate.

MATTRIAL AND METHODS

12 normal fullterm infants constitute the subject material for the study. They were all products of normal gestations and uneventful deliveries. Their birthweights varied between 3190 and 3920 g.m. With respect to age the material may be divided in 3 groups. 4 infants were 1—2 hour old, 4 were 19—23 hours old, and the remaining 4 were between 18 and 58 hours old at the time of the study. Infants in the two latter groups were investigated not earlier than 2 hours after a feeding. The babies were covered with two layers of sterile cloths and were apart from the heat radiating from the operating lamp not exposed to any heating devices. Room temperature was kept at 25—26 C, and the infants were all asleep during the investigation.

Blood pressure measurements. Pressures in the abdominal aorta were recorded via a polyethylene tube (Sterilon P 5) inserted through one of the umbilical arteries. Pressure pulse tracings were made on a direct writing recorder with a simultaneous ECG signal. Systemic mean pressure was calculated from the electrically filtered aortic pressure curve.

Peripheral blood flow. The circulation in the left calf of the infant was measured by venous occlusion plethysmography with an air filled cuff as plethysmograph (8). The width of the cuff was 5 cm and the circumference 9.5—10.5 cm, and it fitted snugly around the middle portion of the calf. Double-cuff occlusion at sub-diastolic values was used to cut off the venous circulation according to principles discussed in the literature (10, 9). The plethysmographic cuff was inflated to 5 cm H_2O and pressure variations occurring in the cuff were recorded together with aortic pressure and the ECG. The limb under study was raised and kept at a level corresponding to the mid axillary line during the investigation. When a steady baseline was obtained venous occlusion was induced by valves preset at 40 mm Hg. The plethysmograph was calibrated with 0.1 ml of air from a Mantoux syringe. A series of tracings was made in quick sequence, the mean of 3 technically good tracings being considered representative for the studied limb. Flow per unit volume tissue was figured by computing tissue volume covered by the plethysmograph. Resistance to blood flow was calculated from the plethysmographic flow values and the simultaneously recorded aortic mean pressure. No allowance was made for right atrial pressure.

Cutaneous blood flow was monitored by continuous recording of the skin temperature of the contralateral calf.

In order to evaluate the effect of blood volume depletion on plasma dilution hematocrit recordings were made in a group of infants before the blood volume depletion and 10, 20, and 30 minutes after.

Blood volume reduction. After an initial basal recording of the various parameters studied, blood volume depletion was induced stepwise by withdrawing into a heparinized syringe first 7.5 per cent of predicted total blood volume (PTBV) and then another 7.5 per cent. Recordings of blood flow, pressure, skin temperature and hematocrit were made after every stage. When 15 per cent of PTBV had been removed the infant was left asleep for 15 minutes, following which a new set of recordings was made and the blood reinfused. After a final observation immediately following restitution of blood volume the catheter was pulled out. Care was taken to ensure that recordings were not made on

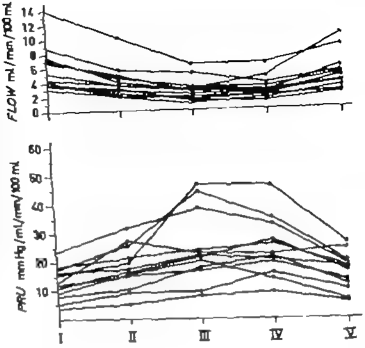

Fig. 1 Peripheral blood flow and vascular resistance as measured in the calf of the newborn infant during graded hypovolemia. PRU = peripheral resistance units. Roman symbols: I = control observation. II = depletion with 7.5 per cent of PTBV. III = depletion with 15 per cent of PTBV. IV = observation 15 minutes after induction of the 15 per cent depletion. V = blood volume restored.

mediately after a spontaneous movement of the leg or foot.

Statistical analyses of data was performed according to standard methods on an IBM 1130 Data Processor.

RESULTS

Pertinent data from the investigation are listed in Table I and values for peripheral blood flow and vascular resistance are also graphically presented in Fig. 1. The aortic mean pressure decreased an average of 2.7 mm Hg after 7.5 per cent depletion and another 5.8 mm Hg when the total amount withdrawn was 15 per cent of PTBV. Prior to the re-infusion of blood arterial mean pressure had risen an average of 2.6 mm Hg as compared to the value recorded immediately after withdrawal. Re-infusion of the blood resulted in an aortic mean pressure overshoot of 3 mm Hg as compared to the control value.

Mean peripheral blood flow was 3.9 ml/min/100 ml for all subjects prior to depletion. The average resistance was 12.5 mm Hg/ml/min/100 ml. Peripheral blood flow decreased and resistance increased in every case after withdrawal of blood.

During the first stage of depletion, peripheral blood flow decreased an average of 34 per cent or 2.0 ml/min/100 ml, and vascular resistance increased 5.2 units or 41 per cent. Both these changes are statistically highly significant ($p<0.01$). Peripheral blood flow decreased another 19 per cent and vascular resistance increased another 53 per cent as compared to the control values ($p<0.01$) after 15 % depletion. The total blood flow reduction in the calf after a 15 per cent reduction of PTBV thus amounted to 53 per cent with a concomitant increase

Both these changes are statistically highly significant ($p<0.01$). Peripheral blood flow decreased another 19 per cent and vascular resistance increased another 53 per cent as compared to the control values ($p<0.01$) after 15% depletion. The total blood flow reduction in the calf after a 15 per cent reduction of PTBV thus amounted to 53 per cent with a concomitant increase

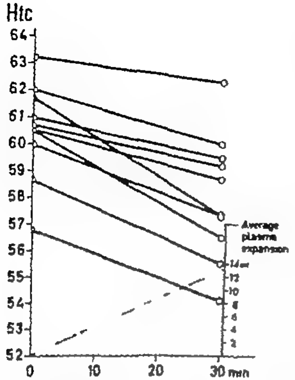

Fig 2 Change in hematocrit reading during the hypovolemic situation Shaded area represents estimated plasma volume expansion

in vascular resistance of 94 per cent. Reappraisal of the situation after 15 minutes showed an inconstant pattern and the average values for flow and resistance did not change

Whereas in two cases the peripheral blood flow was significantly higher after restitution and vascular resistance less than before depletion, the majority of cases had lower peripheral flow and higher resistance at the end of the investigation

Temperature response Rectal temperature was usually very well maintained with an average increase during hypovolemia of +0.2°C. Changes in cutaneous temperature were small and inconsistent with an average increase during hypovolemia of 0 03 C. Actual temperature changes in the individual cases are listed in Table 1

Hematocrit response Numerical values for the venous hematocrit are listed in Table 1 and the change in hematocrit is graphically reproduced in Fig 2 for the approximately 25-minute period between the first withdrawal and the restitution of blood volume. The average fall in hematocrit during this time period amounted to 2.31 per cent. There was no indication that the drop in hematocrit was related to the initial hematocrit reading

The magnitude of the parameters studied did not seem to be correlated to the age of the patient nor to the weight group.

DISCUSSION

Various types of venous occlusion plethysmography have been used in earlier investigations of the peripheral blood flow of the newborn infant. Riley (22) who was the first to apply the technique quantitatively to the newborn, used an air filled plethysmograph and reported a mean blood flow in the hand and forearm of the full term newborn infant of 5.2 ml/min/100 ml. Celander (3) working with a water filled plethysmograph covering the foot and calf of the infant arrived at mean values of 7 9 ml/min/100 ml in the healthy newborn. In a recent study (14) an average value of 9 6 ml/min/100 ml is given for the calf blood flow with a straingauge plethysmographic principle where volume changes are recorded as variations of the impedance of a conducting system encircling the limb studied The present figures of 5 9 ml/min/100 ml tissue for the calf of the fullterm infant as well as those of Riley using the same technique are thus somewhat lower than those reported with different plethysmographic techniques Existing differences may probably be explained by dissimilarities

TABLE I

Table I Data on the peripheral circulatory pattern in twelve infants during graded hemorrhage Roman symbols I—V represent control observation, depletion with 7.5 per cent of PTBV depletion with 15 per cent of PTBV prolonged observation after 15 per cent depletion and observation after restitution of blood volume, respectively HR = heart rate PF = peripheral blood flow SD = standard deviation. PRU = peripheral resistance units. HTC = hematocrit. ST = skin temperature RT = rectal temperature x, xx, xxx interposed between two figures relates to the degree of statistically significant difference (x = 0.05 > p > 0.01 xx = 0.01 > p > 0.001 xxx = p < 0.001) Symbols below figures in Stage V relate to comparison with control observation.

in the methodology and to some extent by different experimental conditions. As existing differences between various methods have no bearing on the interpretation of the present results since each patient serves as his own control, they may be neglected.

The hemodynamic response of the infant to moderate hypovolemia with well maintained systemic blood pressure closely reflects the findings in an earlier investigation on the central circulatory pattern during blood volume depletions of identical magnitude (29). The increase of peripheral resistance that was observed in the earlier investigation has been verified in this study and quantitated with respect to vascular response of the lower limb. The observed *increase in* peripheral resistance seems to be directly proportional to the *degree of hypovolemia*. It is evident that during the 15 per cent depletion, resistance to blood *flow* in the calf of the infant *is almost doubled*. The finding that the average increase in peripheral resistance is considerably larger in the calf than the calculated increase in resistance to flow in the ascending aorta during identical volume depletion suggest the presence of *vascular* compartments where

infants followed with hematocrit determinations, calculation of the amount of fluid transudated or the percentage of blood volume restoration may be made. For the present material this volume of transudated fluid amounts to 13 ml during the 25-minute interval or an approximate 25 per cent restoration of depleted volume by the time blood is being reinfused. Since the hypovolemia in the present investigation was induced stepwise and the hematocrit determined only once initially and again just prior to the reinfusion of blood, the rate and other characteristics of this fluid transfer cannot be more specifically analysed from the present data. In order to augment these observations a series of 5 infants with comparable birthweight and age were investigated exclusively with respect to changes in hematocrit during prolonged hypovolemia. Readings were made from 5—6 samples taken before and 10, 20 and 30 minutes after the withdrawal of 15 per cent of PTBV. The results are graphically plotted in Fig. 3. It is evident that the fastest plasma expansion takes place immediately after blood withdrawal and that after 10 minutes some 20 per cent of the depleted volume has been restored. The total plasma dilution during the 30-minute observation period amounts to some 30 per cent of the withdrawn volume.

Plasma volume expansion after graded hemorrhage has been extensively studied since Starling first stated (26) that posthemorrhagic dilution of blood took place in an effort to restore the circulating blood volume. It has been concluded from animal experiments (21) that the capacity of plasma volume dilution is great enough to restore within a few hours the plasma volume depleted during hemorrhage up to 50 per cent of the TBV. It has also been demonstrated (20) that the posthemorrhagic plasma volume is significantly greater after 24 hours than control values, thus reflecting an attempt to restore the total blood volume. Whereas in the early phases of plasma restoration the mechanism is purely a dilution, in later phases protein concentration rises and attains control values 2 hours post hemorrhage (20).

The presence of a fairly rapid restoration of blood volume in the absence of marked systemic hypotension indicates that it is not systemic pressure per se which is controlling the watershift in the newborn infant. This is in good agreement with results in animals (25, 30) which attest that capillary and not systemic pressure is involved in this mechanism. Experimental investigations in ani-

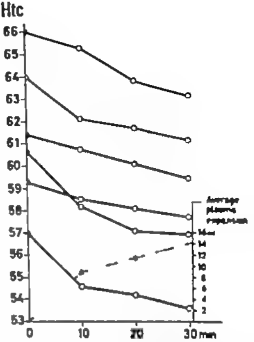

Fig. 3. Change in hematocrit reading after one-step withdrawal of 15 per cent of PTBV. Shaded area represents estimated plasma volume expansion.

vascular response to bleeding is less pronounced or does not exist.

Whereas it is accepted that most of the vascular compartments of the body are in some way engaged in the maintenance of blood pressure homeostasis, the vascular response in some is absent or indefinite. It is well documented that the cerebral blood flow is autoregulated securing perfusion to the brain in the presence of systemic hypotension (2 15) It has also been suggested that the vascular resistance of the skin should not be directly engaged in overall systemic blood pressure control during hemorrhage (12) As the perfusion of these two vascular regions alone in adult man amounts to some 20—30 per cent of the cardiac output, it is easily understood that in the newborn infant, where both spaces are relatively larger these low resistance compartments must be reflected in the central flow resistance

Studies of the regional blood flow in the newborn infant have demonstrated that both cutaneous perfusion (1) limb perfusion (5 6) and possibly also renal blood flow (18) are subject to considerable vasomotor control and seem to react to proper stimuli much the same as the circulation in adult man Our findings imply that the general pattern of response to hypovolemia, with a redistribution of blood in a centripetal direction is the same in the newborn infant as in grown-ups It would seem from the skin temperature recordings that during thermal stability cutaneous circulation does not play a great role in raising the peripheral resistance to conserve systemic blood pressure. Recent findings (19) that skin temperature is reduced as a consequence of blood volume deprivation at the time of birth may imply that the considerably smaller blood volume found in early clamped infants may also be a strong enough stimulus to engage the vasomotor control of the skin in blood pressure homeostasis. A more accurate explanation may however be that the lower skin temperature in these infants is due to thermoregulation, an activity which requires and responds drastically with cutaneous vasomotor regulation

The establishment of a centralized blood perfusion has earlier been demonstrated during neonatal stress (6 23) and also experimentally verified during oxygen deprivation (24) Whereas peripheral vasoconstriction in skeletal muscles evidently is capable of maintaining systemic blood pressure by the centralisation of the blood volume, this is performed at the expense of local muscular blood supply with potential metabolic consequences It is, however well known that perfusion of the resting muscle in man is far greater than the metabolic need with an a v oxygen difference usually not in excess of 30 per cent saturation. Knowing that peripheral perfusion in the newborn infant is almost twice that of the adult (6) it is reasonable to assume that the blood supply to the limb muscles of the newborn must be considerably more reduced than is the case in the present study to be inadequate for the metabolic need of the tissue

Although the circulatory pattern did not seem to be significantly affected by the 15 minutes of prolonged hypovolemia, hematocrit readings indicate that the blood volume deficit is being partly compensated for by restitution of the plasma volume The finding of a mean 3 per cent hematocrit decrease during the 25 minute period between the first withdrawal and the restitution of blood volume reflects fluid transudation from the extravascular compartment Estimating an average PTBV for the 10

infants followed with hematocrit determinations, calculation of the amount of fluid transudated or the percentage of blood volume restoration may be made. For the present material this volume of transudated fluid amounts to 13 ml during the 25-minute interval or an approximate 25 per cent restoration of depleted volume by the time blood is being reinfused. Since the hypovolemia in the present investigation was induced stepwise and the hematocrit determined only once initially and again just prior to the reinfusion of blood, the rate and other characteristics of this fluid transfer cannot be more specifically analysed from the present data. In order to augment these observations a series of 5 infants with comparable birthweight and age were investigated exclusively with respect to changes in hematocrit during prolonged hypovolemia. Readings were made from 5—6 samples taken before and 10, 20 and 30 minutes after the withdrawal of 15 per cent of PTBV. The results are graphically plotted in Fig. 3. It is evident that the fastest plasma expansion takes place immediately after blood withdrawal and that after 10 minutes some 20 per cent of the depleted volume has been restored. The total plasma dilution during the 30-minute observation period amounts to some 50 per cent of the withdrawn volume.

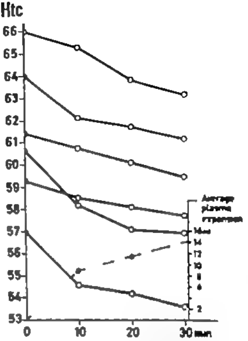

Fig. 3. Change in hematocrit reading after one-step withdrawal of 15 per cent of PTBV. Shaded area represents estimated plasma volume expansion.

Plasma volume expansion after graded hemorrhage has been extensively studied since Starling first stated (26) that posthemorrhagic dilution of blood took place in an effort to restore the circulating blood volume. It has been concluded from animal experiments (21) that the capacity of plasma volume dilution is great enough to restore within a few hours the plasma volume depleted during hemorrhage up to 50 per cent of the TBV. It has also been demonstrated (20) that the posthemorrhagic plasma volume is significantly greater after 24 hours than control values, thus reflecting an attempt to restore the total blood volume. Whereas in the early phases of plasma restoration the mechanism is purely a dilution, in later phases protein concentration rises and attains control values 2 hours post hemorrhage (20).

The presence of a fairly rapid restoration of blood volume in the absence of marked systemic hypotension indicates that it is not systemic pressure per se which is controlling the watershift in the newborn infant. This is in good agreement with results in animals (25, 30) which attest that capillary and not systemic pressure is involved in this mechanism. Experimental investigations in ani

mals have also revealed that during post hemorrhagic plasma expansion transudated liquid is coming from selective areas, one of which is the interstitial compartment of the skeletal muscles (30)

Although it would be difficult and probably meaningless to compare the rate at which plasma is expanded in the experimental animal with that of the newborn, it is of interest to note that the capacity of the newborn human infant to restore plasma volume seems to match that of other species

In view of the fact that the present investigation has shown that there is a very rapid restoration of plasma volume after induced hypovolemia in the newborn the findings in infants with early clamped umbilical cord where considerably more blood may be withheld seems somewhat confusing It has been repeatedly shown (4 16 27) that, whereas infants with late umbilical cord clamping steadily increase their hematocrits as a sign of hemoconcentration, earlyclamped infants who are deprived of presumably 50—100 ml of blood maintain stable hematocrits during the first 6 hours of life and probably also later The fact that the newborn infant in this situation is not fighting desperately to increase its circulating blood volume must be due either to the possibility that the lower blood volume represents normovolemia for the newborn or that there are in the early-clamped infant considerable vascular compartments closed to circulation The finding of a more pronounced metabolic acidosis in these infants may indirectly support this latter assumption. It has been suggested in an earlier communication (28) that the aeration and establishment of perfusion in the neonatal lung may potentially create a condition of hypovolemia in the newborn infant deprived of the placental transfusion. From the present results it is evident that the newborn infant is capable of restoring plasma volume during conditions of artificially induced hypovolemia. The fact that he does not seem to do this when deprived of the placental transfusion implies that the early-clamped newborn is in volumetric balance

SUMMARY

Twelve newborn infants, 1½ to 58 hours old have been investigated with respect to the consequences of graded hemorrhage on peripheral circulation and plasma volume. It has been demonstrated that the newborn infant responds to a hypovolemia corresponding to 15 per cent of predicted total blood volume with a twofold increase of resistance to blood flow in the calf Peripheral vasomotor tone is adequately controlling the systemic blood pressure by decreasing perfusion of the vascular compartments in the calf muscle whereas no indications of a change in the cutaneous blood flow occurred A rapid decrease of the arterial hematocrit reflects efforts to restore the plasma volume

Among the characteristic features of the premature infant some of the most important pertain to the circulatory system. It has been shown by indirect means (7 10, 13) as well as by direct intravascular observations (14, 15 22) that the premature newborn has significantly lower systemic blood pressure than the infant born at term. It has also been demonstrated that the peripheral circulation of the premature infant is characterized by lower vascular resistance and higher blood flow per unit tissue than in the fullterm newborn (3, 11 21).

Although some difficulties exist in relating the magnitude of the peripheral blood flow studied in one section of a limb to the overall cardiac output, it might be expected that the left ventricular minute volume per unit BSA or body weight should be greater or at least equal to that recorded in fullterm infants. The existence of left-right shunts in the postnatal period may added to a higher systemic demand for perfusion, be expected to tax the left ventricular capacity more than in the newborn infant at term.

The frequent occurrence of atelectases in the immature infant must be regarded as not only a respiratory complication but also potential circulatory hazard. Apart from the hypoxic effect caused by perfusion of non-ventilated areas of lung, the overall increase in pulmonary vascular resistance secondary to atelectasis (19) may result in extra-pulmonary bypass with reduced pulmonary blood flow and increased venous admixture to the systemic circulation.

It has been considered of great importance to study with the aid of earlier described modifications of the Stewart Hamilton technique (8) the central circulatory pattern of the immature infant with and without pulmonary pathology and relate it to the simultaneously assessed peripheral circulation as well as to earlier reported findings in fullterm infants. It was judged equally important from the pathogenetic and possibly also from therapeutic points of view to elucidate possible differences in the circulatory pattern between these three groups of newborn infants. The present communication reports the preliminary results from an investigation which is currently being carried on in our departments.

MATERIAL AND METHODS

10 premature infants consecutively admitted to the neonatal service of the University Hospital, Helsinki, Finland, constitute the material for the investigation. Five of the infants were normal prematures without signs of cardiopulmonary impairment as judged by the lack of cyanosis in room air respiratory rate below 60/min, and without abnormal respiratory retractions. Plain chest x-ray films revealed no pulmonary or cardiovascular pathology in any of these 5 infants. Their birth weights ranged from 1590 to 2290 gm, and their gestational age from 30 to 35 weeks. Apart from close incubator surveillance and in some instances tube feeding, these infants did not receive any specific treatment. Their stay in the hospital was judged uneventful and was terminated as soon as feeding difficulties disappeared.

The remaining 5 patients all exhibited various degrees of respiratory distress at the time of the study They all had cyanosis while breathing room air respiratory retractions and tachypnea. Radiological examination of the lungs showed the characteristic fine granulated, mottled appearance of hyaline membrane disease. No instances of pneumothorax, emphysematous changes or larger atelectatic areas were identified in the x ray study which was performed just prior to the circulatory investigation. These infants were all breathing 100 per cent oxygen at the time of study Three of the infants in this group had severe pulmonary impairment with aortic blood PO_2 below 60 mmHg while breathing 100 per cent oxygen. The distressed infants were routinely treated with sodium bicarbonate and glucose intravenously (transumbilical route) to combat the metabolic acidosis This treatment was only temporarily interrupted during the study Three of these infants were sick enough to be considered suitable candidates for intermittent positive pressure breathing (IPPB) Whereas the most severely affected baby (n:o 9) who expired at age 4 days from the disease was connected to the respirator (Bennett Mod.PR2) prior to the circulatory study and was kept on assisted ventilation during the investigation, the other 2 were submitted to this treatment the following day The remaining 2, least affected infants ran a less dramatic course with spontaneous recovery and were free of symptoms at the age of 6—10 days. The child who expired exhibited typical pulmonary pathology of hyaline membrane disease. The infants in the respiratory distress group varied in birth weight from 1290 to 1880 gm, and their gestational age from 31 to 34 weks Further data pertaining to the whole material are listed in *Table I*

The techniques used for the study of the central as well as peripheral circulation have been described in some detail in foregoing communications (8) All infants were investigated laying on the extractable tray of an Isolette[1] Incubator The automatic heat control of the incubator was engaged and whenever neccessary additional heat was provided by a radiating lamp It was usually easy to maintain body temperature with the automatic temperature control unit monitored by a rectal probe

For the peripheral studies, the right leg of the infant was raised to approximately sternal level and the plethysmographic cuff with a circumference of 8.5—9 5 cm and width of 2 5 cm was attached to the leg just distal to the knee. The proximal occlusion was applied to the mid portion of the thigh. Plethysmographic pressure was kept at 5 mm Hg and occlusion pressures at 30—40 mm Hg When a good basal state was attained 3 recordings were made in rapid succession, the leg was lowered again, and the cuffs removed The baby was now covered with sterile cloths and one of the umbilical arteries and the umbilical vein catheterized with a F 5 feeding tube. The venous catheter was advanced to the right atrium where blood was withdrawn for gas analyses. The arterial catheter was placed in the ascending aorta where blood samples were collected for analyses. Right atrial position of the venous catheter was checked by pressure recordings and gas analyses and the position of the aortic catheter by pull back from the left ventricle (4 cases) or by the detection of a ductal shunt in the ascending aorta-to-left atrial dye dilution study

In addition to right atrial and ascending aorta samples blood was also taken from the

left atrium for blood gas analyses. Determinations of pH, PCO_2 and PO_2 were made with an Astrup micro-assembly (Radiometer, Denmark) and hemoglobin was determined by standard procedures. Pressures in the aorta and atria were monitored on an oscilloscope and recorded on a direct writing instrument (Mingograf 34, Elema Schönander). The calculation of resistance to blood flow was made from the electrically filtered mean pressure recorded in the ascending aorta without corrections for right atrial pressures.

The left ventricular output (LVO) was estimated by the dye dilution principle according to methods earlier described (8). Indicator material (Cardiogreen®) was injected into the left atrium, blood being sampled from the ascending aorta. A modified concept (8) of the forward triangle formula (13) was used for the calculation of left ventricular output. Densitometer calibration was performed with the infant's own blood in two 5 ml syringes well mixed with known amounts of dye. Virtually no blood was lost during the investigation since withdrawn blood was reinfused after calibration and subsequent dye curves.

The magnitude of the right-left shunt through the foramen ovale was estimated by injection of dye into both right and left atria and sampling from the ascending aorta (26). The magnitude of the left-right shunt through the ductus arteriosus was calculated according to techniques described in the literature (12). Pulmonary blood flow was considered identical with the left ventricular output minus existing right-left shunt through the foramen ovale.

The intrapulmonary admixture of venous blood,[1] i.e. non-effective pulmonary blood flow, was computed from the values for pulmonary and left ventricular blood flow, the oxygen content of right atrial, ascending aortic and mixed venous blood (5). The latter figure was derived from values for the left-right ductal shunt and the oxygen content of right atrial and ascending aortic blood. The oxygen content of the various blood samples was computed from oxygen saturation figures corresponding to the temperature and pH corrected PO_2 values (17, 23). Although the resulting figures for intrapulmonary venous admixture must be considered only gross approximations, due primarily to instability of the circulatory pattern, it was considered of interest to make a comparison of this factor in the two groups studied.

RESULTS

The results of the present investigation are listed in Table I together with other data pertaining to the 10 premature infants studied. The mean value for LVO and Cardiac Index is approximately 20—25 % smaller in the group with distressed infants. The mean aortic pressure is reduced correspondingly in the respiratory distress (RD) group and the central resistance to blood flow, accordingly, remains unchanged. Whereas the left-right ductal shunt seems to be of the same magnitude and frequency in the two groups, the right-left shunt through foramen ovale is approximately twice as great in the RD group. Added to the difference in LVO this results in a marked difference in pulmonary blood flow (PBF) between the two groups. This difference which averages 223 ml/min is also statistically probably significant ($p<0.05$). Venous admixture to pulmonary venous blood (VA) is almost twice as large in the

---

1 see appendix

distressed group, amounting to nearly 30 per cent of the total pulmonary blood flow. The peripheral circulatory pattern did, somewhat surprisingly, not differ very much between the groups. It is only in the most severely affected child that peripheral vascular resistance is very elevated and peripheral blood flow correspondingly reduced to less than 1 ml/min/100 ml tissue.

Although many of the mean values of the various parameters studied differ considerably between the two groups, it is only the difference in calculated pulmonary blood flow that has a degree of statistical significance. It should be mentioned in this regard that the magnitude of the central shunts which partially constitute the basis for calculation of PBF and VA varied considerably in the same patient irrespective of the clinical condition of the infant. The value used for the calculation of the above parameters was that measured temporally nearest to other inter-related observations.

DISCUSSION

The results of the present investigation may be discussed from two standpoints. The first involves a comparison with data obtained in fullterm infants to elucidate possible differences with respect to the quantitative circulatory pattern between term newborn infants and healthy premature infants. The second point of interest concerns the differences in the circulatory pattern recorded in premature infants with and without respiratory distress and the identification of characteristic hemodynamic features of the disease.

Relationships between term newborn infants and premature infants without respiratory distress. In an earlier communication from this laboratory (1) circulatory data including quantitation of cardiac output were reported for a group of late-clamped infants born at term. These infants may from the circulatory point of view be considered representative for the normal fullterm. Circulatory data obtained in a group of these late-clamped infants in the same post partum age range as the present material has consequently been used as control material.

A comparison between the circulatory data in these two groups of infants substantiates the suspicion that the premature newborn has a relatively much higher cardiac output than the infant born at term. Whereas in the late-clamped fullterm infants 2—24 hours old the cardiac index was found to be 3.31 L/min/M²BSA, the corresponding figure for the healthy premature was 5.5. The finding that the resistance to central flow in the premature is only slightly more than ⅓ of the 28.7 mm Hg/L/min/M²BSA reported for the term infants suggests that the actual work of the left ventricle in the premature infant is only moderately increased. This is illustrated by the finding that left ventricular work index (kgm/min/M²BSA) is 3.5 in the premature as compared with 2.8 for the fullterm infants. The lower resistance to central blood flow is parallelled by a lower peripheral vascular resistance, where the value 8.8 mm Hg/ml/min/100 ml compares with 1..3 reported earlier for *fullterm infants* of the same age (27).

The presence of large left-right shunts through the ductus arteriosus in some of the premature infants studied makes it difficult to assess the effect of pulmonary vascular resistance on the computed central resistance (CRU) values. The fact that the CRU value is approximately the same whether or not the left-right ductal shunt is present suggests that the resistance to central blood flow is

left atrium for blood gas analyses. Determinations of pH, PCO_2 and PO_2 were made with an Astrup micro-assembly (Radiometer Denmark) and hemoglobin was determined by standard procedures. Pressures in the aorta and atria were monitored on an oscilloscope and recorded on a direct writing instrument (Mingograf 34 Elema Schonander). The calculation of resistance to blood flow was made from the electrically filtered mean pressure recorded in the ascending aorta without corrections for right atrial pressures.

The left ventricular output (LVO) was estimated by the dye dilution principle according to methods earlier described (8). Indicator material (Cardiogreen®) was injected into the left atrium, blood being sampled from the ascending aorta. A modified concept (8) of the forward triangle formula (13) was used for the calculation of left ventricular output. Densitometer calibration was performed with the infant's own blood in two 5 ml syringes well mixed with known amounts of dye. Virtually no blood was lost during the investigation since withdrawn blood was reinfused after calibration and subsequent dye curves.

The magnitude of the right-left shunt through the foramen ovale was estimated by injection of dye into both right and left atria and sampling from the ascending aorta (26). The magnitude of the left-right shunt through the ductus arteriosus was calculated according to techniques described in the literature (12). Pulmonary blood flow was considered identical with the left ventricular output minus existing right-left shunt through the foramen ovale.

The intrapulmonary admixture of venous blood[1] i.e. non-effective pulmonary blood flow was computed from the values for pulmonary and left ventricular blood flow the oxygen content of right atrial, ascending aortic and mixed venous blood (5). The latter figure was derived from values for the left-right ductal shunt and the oxygen content of right atrial and ascending aortic blood. The oxygen content of the various blood samples was computed from oxygen saturation figures corresponding to the temperature and pH corrected PO_2 values (17, 23). Although the resulting figures for intrapulmonary venous admixture must be considered only gross approximations due primarily to instability of the circulatory pattern, it was considered of interest to make a comparison of this factor in the two groups studied.

RESULTS

The results of the present investigation are listed in Table I together with other data pertaining to the 10 premature infants studied. The mean value for LVO and Cardiac Index is approximately 20—25 % smaller in the group with distressed infants. The mean aortic pressure is reduced correspondingly in the respiratory distress (RD) group and the central resistance to blood flow accordingly remains unchanged. Whereas the left-right ductal shunt seems to be of the same magnitude and frequency in the two groups, the right-left shunt through foramen ovale is approximately twice as great in the RD group. Added to the difference in LVO this results in a marked difference in pulmonary blood flow (PBF) between the two groups. This difference, which averages 223 ml/min, is also statistically probably significant ($p<0.05$). Venous admixture to pulmonary venous blood (VA) is almost twice as large in the

[1] see appendix

resistance. As this infant was the only one who was ventilated with IPPB during the investigation it may be questioned whether the increased intrapulmonary pressure may have been responsible for the reduced cardiac output. This is known to occur in the healthy lung (28). Restudying the pressure curves from the right and left atria, however, we were able to show that the pressure transmitted to the circulatory system was only a fraction of that applied to the airways and interference with the circulatory dynamics might hence be considered small. It is reasonable to suggest that the applied pressures are absorbed by the stiffened lung parenchyma.

The only available data in the literature related to the quantitative aspects of the circulation in premature infants with respiratory distress are those of Chu et al (4) and Stahlman et al (24), both unfortunately without critical evaluation of the methods used for determination of cardiac output and pulmonary blood flow. While the former group is able to show a reduced effective pulmonary blood flow in affected infants, the latter suggests that pulmonary perfusion in toto may be higher than in the normal premature infant. Our results are opposed to the latter statement but seem to agree with the suggestion of Chu et al. Whereas these authors report an effective pulmonary circulation in the range of 100—150 ml/min in RD cases as compared to 300—450 in normal prematures, corresponding figures in our material are calculated to 350 and 640 ml/min respectively.

The matter of intrapulmonary venous admixture in normal and respiratory distress cases has been studied rather intensely in the past years. Berggren (2) postulated that breathing oxygen for a period of 20—30 minutes would entirely abolish all venous admixture due to diffusion disturbances and a remaining desaturation in arterial blood is explained by the presence of real right-left shunts. Whereas it has been possible earlier to demonstrate with this technique the presence of a true right-left shunt in the newborn infant (15, 16, 18, 20, 25), it has not been possible to separate the intrapulmonary fraction of this shunt from the overall venous admixture. The presence of an intrapulmonary venous admixture, which has been possible to identify and quantitate with the present technique during oxygen breathing, suggests the presence of a true intrapulmonary right-left shunt in the distressed infants. As no circulatory quantitations were performed during oxygen breathing in the healthy prematures the two groups are not directly comparable. It may nevertheless be of interest to observe that venous admixture in the distressed group in spite of oxygen breathing was well above the average for the healthy group in four of the five patients. This indicates that the part of the venous admixture which is due to true right-left shunting within the lung is relatively much greater in the affected infants than would be suggested from the difference in the average VA figure.

It would seem that the pathophysiological background for the cyanosis commonly accompanying respiratory distress in the newborn infant is at least twofold. Whereas the intrapulmonary venous admixture during oxygen breathing is with all probability secondary to a diminished ventilation/perfusion ratio, the extrapulmonary right-left shunt is related to the reduced pulmonary blood flow and/or impairment of right ventricular function. The therapeutic implications affirm that these infants should be treated to improve the pulmonary ventilation as well as perfusion.

mainly governed by other vascular compartments. Whereas big left-right ductal shunts were common findings in both groups the presence of right-left shunts through the foramen ovale in all the studied prematures is contrary to the finding in full-term infants (1) where shunts at this level were rare. In spite of the presence of shunts at the atrial level the pulmonary blood flow in the normal premature infants considerably exceeded that of infants at term with an average figure of 5.0 L/min/M²BSA, approximately 50 per cent in excess of the value reported for fullterm infants (1).

It may thus be concluded that the normal premature infant with respect to central circulatory pattern is characterized by a hyperkinetic circulation as compared to the infant at term. This seems to apply both to the systemic and pulmonary circulation. Other characteristic features of the premature's circulation are the findings of right-left shunt on the atrial level as well as a lower vascular resistance.

The first report involving circulatory data from a large group of premature infants without pulmonary complications is that of Moss et al (15) where the circulatory pattern was analysed from blood pressure and blood gas determinations. These authors concluded that right-left shunting through the ductus arteriosus was uncommon in these infants just as in fullterm infants, and were able to show that systemic but not pulmonary arterial blood pressure was related to the weight of the infant. Although their technique did not allow identification of right-left atrial shunts, the overall venous admixture to systemic blood is approximately of the same magnitude as in the present material.

Relationships between the circulatory pattern of premature infants with and without respiratory distress. The circulatory evaluation of the premature infants with RD suggests that there is considerably lower cardiac output and pulmonary blood flow associated with a higher venous admixture and peripheral resistance. The difference is statistically significant only with respect to pulmonary blood flow ($0.02 < p < 0.05$) a finding which is not surprising in view of the small number of cases studied. It may be argued that the two groups of infants are not directly comparable due to differences in birthweight with the smaller infants usually exhibiting RD. The previous comparison between infants of normal birthweight and the prematures, however, suggests that if a systemic difference is introduced due to difference in birthweight it would be expected to increase rather than decrease the cardiac output in the lighter weight group. It may also be questioned whether the fact that the RD infants were all breathing pure oxygen at the time of the investigation may have introduced a systematic difference in the circulatory pattern. The effect of oxygen on the pulmonary arterial circulation, however, would if anything tend to diminish pulmonary vascular resistance (6) and consequently be responsible for an increase of the pulmonary circulation in the RD infants. It may accordingly be suggested that the overall pulmonary as well as systemic blood flow is smaller in distressed prematures and that both extra- and intrapulmonary venous admixture is increased. It is probably significant that these differences were far most accentuated in the severely affected infant who had systemic and pulmonary perfusion amounting to only ⅓ of the average recorded for non-affected prematures. It is also of interest to note that this infant is the only one who showed a dramatically reduced peripheral circulation with high peripheral

SUMMARY

Ten premature infants were investigated with respect to central and peripheral circulatory patterns. Five of the patients had the typical picture of respiratory distress syndrome of varying severity whereas the rest were free of pulmonary pathology. The circulation in the premature infants without respiratory distress is characterized by pulmonary as well as systemic hyperkinesis and the presence of small right left shunts through the foramen ovale. In contrast to the findings in healthy premature infants, the respiratory distress cases usually had a low systemic and pulmonary perfusion with pronounced intra — as well as extra pulmonary right left shunts.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the technical support given by Mrs Ingrid Werner. Sincere thanks are due the nursing personnel of the Premature Infant Unit, University Hospital, Helsinki.

APPENDIX

THE MYTH OF ECHO

The Boeotian ymph Echo had made Hera angry and was punished by being deprived of speech except for the power to repeat the last words spoken by another

She fell in love with the beautiful Narcissus, son of Cephissus, the River God. Narcissus was annoyed with her endless repetitions and repelled her love.

Her grief made Echo wither wa until only her voice was left in the woods and upon the mountains.

When Narcissus once admired his reflection in well the Goddess of Love, Aphrodite, made him fall in love with his own reflection in order to avenge the ymph.

THE MYTH OF ECHO

The Boeotian nymph Echo had made Hera angry and was punished by being deprived of speech except for the power to repeat the last words spoken by another

She fell in love with the beautiful Narcissus, son of Cephissus, the River God. Narcissus was annoyed with her endless repetitions and repelled her love.

Her grief made Echo wither away until only her voice was left in the woods and upon the mountains.

When Narcissus once admired his reflection in well the Goddess of Love, Aphrodite, made him fall in love with [illegible] own reflection in order to avenge the nymph.

INTRODUCTION

There has long been a need in paediatrics for a harmless and simple method of recording the intracranial anatomy particularly deviations in size of the ventricular system.

Since the introduction of more active treatment of neuropaediatric patients, for example shunt operations in expansive hydrocephalus, this need has become even more urgent.

An expansion of the ventricular system is not always reflected in variations in cranial size considerable ventricular dilatation may occur at the cost of the cerebral parenchyma without any increase in the cranial circumference, while relatively great cranial enlargement may occur physiologically and without any abnormal widening of the ventricles, for example in premature babies. Only in its more advanced stages can hydrocephalus be diagnosed by transillumination and photographic recording of the abnormalities with this method is a complicated procedure. Cerebral pneumography is the supreme method for detailed study of the ventricular system, but this investigation is time consuming, complicated and not entirely free of risk in infants and small children. Furthermore, the findings at pneumography cannot be repeatedly checked, and after a shunt operation in hydrocephalus it is a dangerous method for follow up examination owing to the risk of gas emboli.

A team study of problems in hydrocephalus has been in progress for several years at the University Hospital in Uppsala (Hadenius et al. 1962, a, b c, Hagberg et al. 1962, Sjögren 1963 Hagberg et al. 1963 Hagberg et al 1964 Sjögren et al. 1964 Sjögren 1964 Sjögren 1965 Granholm & Sjögren 1965 Reuterskiöld & Sjögren 1965 Sjögren et al. 1966, Hagberg & Sjögren 1966, Reuterskiöld & Sjögren 1967). During our discussions on the problems involved in diagnosis and in making decisions for operative procedures, my husband who is a physicist (doctor of technology) expressed his confidence in ultrasonic echo as a diagnostic aid. An ultrasonic apparatus was kindly placed at my disposal by the doctors at the Departments of Neurology and Neurophysiology at this Hospital and my investigations with echoencephalography on hydrocephalic patients began in the autumn of 1962.

INTRODUCTION

There has long been a need in paediatrics for a harmless and simple method of recording the intracranial anatomy particularly deviations in size of the ventricular system.

Since the introduction of more active treatment of neuropaediatric patients, for example shunt operations in expansive hydrocephalus, this need has become even more urgent.

An expansion of the ventricular system is not always reflected in variations in cranial size considerable ventricular dilatation may occur at the cost of the cerebral parenchyma without any increase in the cranial circumference, while relatively great cranial enlargement may occur physiologically and without any abnormal widening of the ventricles, for example in premature babies. Only in its more advanced stages can hydrocephalus be diagnosed by transillumination, and photographic recording of the abnormalities with this method is a complicated procedure. Cerebral pneumography is the supreme method for detailed study of the ventricular system, but this investigation is time consuming, complicated and not entirely free of risk in infants and small children. Furthermore, the findings at pneumography cannot be repeatedly checked, and after a shunt operation in hydrocephalus it is a dangerous method for follow up examination owing to the risk of gas emboli.

A team study of problems in hydrocephalus has been in progress for several years at the University Hospital in Uppsala (Hadenius et al. 1962, a, b, c, Hagberg et al. 1962, Sjögren 1963 Hagberg et al. 1963 Hagberg et al. 1964 Sjögren et al. 1964 Sjögren 1964 Sjögren 1965 Granholm & Sjögren 1965 Reuterskiöld & Sjögren 1965 Sjögren et al. 1966, Hagberg & Sjögren 1966, Reuterskiöld & Sjögren 1967). During our discussions on the problems involved in diagnosis and in making decisions for operative procedures, my husband who is a physicist (doctor of technology), expressed his confidence in ultrasonic echo as a diagnostic aid. An ultrasonic apparatus was kindly placed at my disposal by the doctors at the Departments of Neurology and Neurophysiology at this Hospital and my investigations with echoencephalography on hydrocephalic patients began in the autumn of 1962.

As early as in 1954 Leksell presented his echoencephalographic method (A scan) for studying intracranial anatomy through the intact skull (Leksell 1955). Leksell (1955/56) also pointed out the possibility of diagnosing infantile hydrocephalus by means of echoencephalography This was also discussed by Vlieger & Ridder (1959)

In experimental investigations on autopsy specimens of fresh infantile brains, under conditions as close to normal as possible, Jeppsson (1961) showed it possible to obtain echoes from the interface between brain tissue and cerebrospinal fluid. In another technique Lithander (1961 a) showed that lateral echoes originate in a number of boundary surfaces between brain and cerebrospinal fluid.

Thereafter some investigators (Lithander 1961 b Ford & Ambrose 1963 Schiefer et al 1963 Hemmer 1964 Jacobi & Stephani 1964 West 1964 Umbach & Kley 1965 White et al 1965 Jacobi 1966 Jacobi & Schuch 1966, Lapayoker et al 1966 and others) have considered that echoencephalography is clinically applicable for determining the degree of ventricular dilatation and that it shows "good agreement with cerebral pneumography

However the few more systematic investigations reported, in which echoencephalography has been compared with cerebral pneumography have hardly given convincing evidence that echoencephalography is completely reliable for determining the size of the lateral ventricles in paediatric patients. Thus, Lithander (1961 b) reported 11 children with hydrocephalus in only 8 of whom the lateral ventricle echo was found to be "more laterally situated than normally

From a study of 30 children Mikkelsen (1967) concludes that "only severe central atrophy in children can be diagnosed with certainty"

In the well presented material of Ford & McRae (1966) only three children are included. In a study of newborn infants and adults, Uematsu & Walker (1967) demonstrated enlarged ventricles by echoencephalography in 57 of 64 patients with pneumographically verified ventricular dilatation and also in a further 7 patients who were pneumographically normal West (1967) gave individual data both for the echoencephalographic and the pneumographic values for the widths of the third and lateral ventricles, and concluded that "fairly good agreement was found between the results obtained by the two methods" this conclusion did not pay respect to the fact that differences as high as 47 % were reported between the ultrasonic and roentgenological findings.

However no attempt appears to have been made to analyse the sources of these discrepancies thus, the question is still open as to whether or not it is possible—by a procedure which takes into consideration the special difficulties of evaluating the ventricular size—to rely upon the echoencephalographic findings in an individual paediatric patient.

Preliminary studies (Sjögren 1963, 1964 and 1965) using a method specially adapted for measurement of the ventricular size in infants and children, gave promising results, and comparative studies between this method and cerebral pneumography (to be published) have shown that it is possible to differentiate between normal and dilated ventricular systems in paediatric patients and, further, to determine fairly accurately the size of the lateral ventricles in infantile hydrocephalus. For the purpose of measuring the temporal widths of the ventricles and expressing them in relation to the ultrasonically determined diameter of the head, as indices, I have used the name *echoventriculography (EVG)* so as to emphasize the difference between this echoencephalographic method, developed for infants and children, and the echoencephalographic method used for recording other intracranial structures than the ventricles.

No method of investigation which aims at elucidating the anatomical conditions of the human brain or ventricular system can ever be said to be simple, since in its anatomical construction the brain is such a complex organ. But in comparison with the neuroradiological methods available, the echoencephalographic procedure is extremely simple. However, some small, but most important, practical details and elementary laws of physics regarding the pathways of ultrasound may easily be overlooked; the method requires a knowledge of cerebral anatomy, a sense of form and an ability to think in three dimensions. Furthermore, it has to be kept in mind that human tissues show variations in their acoustic properties at different ages.

This work summarizes some findings from a series of experimental investigations, and presents some physical calculations concerning possible harmful effects of ultrasound in infantile brains, as well as calculations from 700 complete echoencephalographic examinations (see p. 56) in infants and children, with special regard to measurement of the ventricular size. It comprises:

I. some physical aspects concerning ultrasound and infantile osseous and cerebral tissues, and

II. a description of a practical method of examination, and analysis of some sources of error and how they may be eliminated.

Further studies are to be published, comprising:

III. comparative studies, in which the degree of reliability of the presented method is compared with cerebral pneumography with regard to measurements of ventricular size and the diagnosis of cerebral malformations,

IV. an EVG study of normal infants and children, and

V. echoencephalographic follow up studies in patients with hydrocephalus and spina bifida cystica.

In further studies a clinical material will be presented, illustrating some broader aspects of the field of application of this ultrasound technique in paediatrics.

As early as in 1954 Leksell presented his echoencephalographic method (A scan) for studying intracranial anatomy through the intact skull (Leksell 1955) Leksell (1955/56) also pointed out the possibility of diagnosing infantile hydrocephalus by means of echoencephalography This was also discussed by Vlieger & Ridder (1959)

In experimental investigations on autopsy specimens of fresh infantile brains, under conditions as close to normal as possible Jeppsson (1961) showed it possible to obtain echoes from the interface between brain tissue and cerebrospinal fluid In another technique Lithander (1961 a) showed that lateral echoes originate in a number of boundary surfaces between brain and cerebrosp nal fluid

Thereafter some investigators (Lithander 1961 b, Ford & Ambrose 1963 Schiefer et al 1963 Hemmer 1964 Jacobi & Stephani 1964 West 1964 Umbach & Kley 1965 White et al 1965 Jacobi 1966 Jacobi & Schuch 1966, Lapayoker et al 1966 and others) have considered that echoencephalography is clinically applicable for determining the degree of ventricular dilatation and that it shows "good agreement with cerebral pneumography

However the few more systematic investigations reported in which echoencephalography has been compared with cerebral pneumography have hardly given convincing evidence that echoencephalography is completely reliable for determining the size of the lateral ventricles in paediatric patients. Thus, Lithander (1961 b) reported 11 children with hydrocephalus, in only 6 of whom the lateral ventricle echo was found to be "more laterally situated than normally

From a study of 30 children Mikkelsen (1967) concludes that only severe central atrophy in children can be diagnosed with certainty

In the well presented material of Ford & McRae (1966) only three children are included In a study of newborn infants and adults, Uematsu & Walker (1967) demonstrated enlarged ventricles by echoencephalography in 57 of 64 patients with pneumographically verified ventricular dilatation and also in a further 7 patients who were pneumographically normal West (1967) gave individual data both for the echoencephalographic and the pneumographic values for the widths of the third and lateral ventricles, and concluded that fairly good agreement was found between the results obtained by the two methods" this conclusion did not pay respect to the fact that differences as high as 47 % were reported between the ultrasonic and roentgenological findings

However no attempt appears to have been made to analyse the sources of these discrepancies thus, the question is still open as to whether or not it is possible—by a procedure which takes into consideration the special difficulties of evaluating the ventricular size—to rely upon the echoencephalographic findings in an individual paediatric patient.

III DISCUSSION

IV SUMMARY

PART ONE

SOME PHYSICAL ASPECTS OF ULTRASOUND

SOME PHYSICAL ASPECTS OF ULTRASOUND

I GENERAL PROPERTIES

The suitability of ultrasound for medical diagnostic use is due to the fact that high frequency ultrasound possesses beam properties that are subject to the general laws of radiation. Thus ultrasound can be directed as an almost parallel beam. When an ultrasonic beam is transmitted into the body and encounters an interface between tissues with different acoustic impedance (sound velocity x density), part of the ultrasound is reflected against the surface. Ultrasound reflected in this way gives rise to so called echoes.

Concerning the physical properties and effects of ultrasound reference should be made to the special literature of the subject (Bergman 1954) and also to the works of Hertz (1959) and Jeppsson (1961) on echoencephalography In the following a brief review only is given of some physical data concerning ultra sound of relevance for the diagnostic ultrasonic echo investigations presented in this work.

Ultrasound is defined as sound waves with frequencies lying above the human audible range, i. e. exceeding 18—20 kc/sec. For the examinations to be described here, frequencies of 2 Mc/sec and 4 Mc/sec were used.

As with audible sound waves, ultrasound requires a medium through which it can propagate. This medium may be a gas, a fluid or a solid body

The propagation velocity is dependent on the mechanical properties of the medium, such as density and the interaction between the particles in the medium. On the other hand it is largely independent of the sound frequency Cerebrospinal fluid and cerebral parenchyma have similar mechanical properties to water while bone tissue may be regarded more as a solid body (cf Table I).

Ultrasound, when emitted from a plane surface, proceeds with a slightly divergent beam direction the beam becoming increasingly more parallel with increase in frequency The divergency of the beam is determined by the quotient between the wave length and the size of the radiating surface.

The quotient of the reflected intensity and the incident intensity is called the reflection power and the quotient of the transmitted intensity and the incident intensity is called the transmission power. The determining factors for reflection and transmission are the acoustic impedances of the media, with large differences between these acoustic impedances the reflection power approaches 1 and the transmission power approaches zero. This means that at the interface between, for example, a fluid and a gas or a fluid and a solid body the main part of the incident intensity will be reflected (Table II).

Table II. *Reflection power and transmission power at interfaces between different media (according to Jeppsson 1961).*

Interface between	Reflection power $R = I_R/I_0$	Transmission power $T = I_T/I_0$
air — brain	1	0
brain — bone	0.34	0.66
brain — CSF*	0.0003	0.9997

where I_0 = incident sound intensity
I_R = reflected " "
I_T = transmitted " "
and CSF* = 0.154 mol. saline, equivalent to cerebrospinal fluid.

The reflection of ultrasound is determined by the general laws of radiation; thus the angle of reflection is equal to the angle of incidence. On oblique incidence from a liquid into a solid body the ultrasound may be totally reflected. For example, on passage from water to bone tissue (sound velocity for water: 1504, bone tissue: 3380 m/sec, cf. Table I) reflection may occur if the angle of incidence (β) exceeds 27° ($\sin \beta = \sin 90 \times 1504/3380$, $\beta = 27°$).

Calculations

When a sound wave penetrates a body containing interfaces between different media, part of the incident intensity is absorbed on traversing the material. Furthermore, reflection losses occur at the interfaces. If both the absorption coefficients and the acoustic impedances are known for the different media, the intensity of both the penetrating and the reflecting sound waves can be calculated in every point of the body (cf. Jeppsson 1961, p. 80).

The divergency angle $\varrho = 1.22 \times \frac{\lambda}{D}$

where λ = the wave length and

D = the diameter of a circular radiating surface.

If the frequency and sound velocity are known the wave length can be calculated (frequency x wave length = sound velocity) The wave length is an approximate measure of the expected resolution at a frequency of 3 Mc/sec the wave length in water is approximately $^1/_2$ mm. Consequently the uncertainty in the length determination, using ultrasound is in principle at least of this order

When a wave motion traverses a medium some absorption always takes place. This absorption occurs as expressed in the formula

$$I = I_0 \times 10^{-\frac{\alpha d}{10}}$$

where I_0 = the original intensity

α = the attenuation by absorption in dB per unit of length

d = the distance covered, and

I = the intensity when d has been traversed.

Intensity and amplitude (A) are related by the equation $I = A^2$ by taking the square roots, the laws governing the intensity are applicable to amplitudes. Intensity is usually measured in watt/cm² Intensity divided by the sound velocity (v) gives the radiation pressure $P_{rad} = \frac{I}{v}$ N/cm² (Vigoreux 1966)

When an ultrasonic beam strikes the boundary separating two media with different acoustic impedances (Table I) some of the sound is transmitted and part is reflected at the interface.

Table I *Sound velocity density and acoustic impedance for 0 154 mol. saline equivalent to cerebrospinal fluid ("CSF) brain tissue bone tissue and air of room temperature (according to Jeppsson 1961)*

Medium	sound velocity m/sec	density g/cm³	acoustic impedance g/cm² × sec
CSF"	1504	1.005	1.51×10^5
brain	1515	1.028	1.56×10^5
bone	3380	1.8	6.1×10^5
air	333	0.0012	4.0×10^1

The quotient of the reflected intensity and the incident intensity is called the reflection power and the quotient of the transmitted intensity and the incident intensity is called the transmission power. The determining factors for reflection and transmission are the acoustic impedances of the media; with large differences between these acoustic impedances the reflection power approaches 1 and the transmission power approaches zero. This means that at the interface between, for example, a fluid and a gas or a fluid and a solid body, the main part of the incident intensity will be reflected (Table II).

Table II. Reflection power and transmission power at interfaces between different media (according to Jeppsson 1961).

Interface between	Reflection power $R = I_R/I_0$	Transmission power $T = I_T/I_0$
air — brain	1	0
brain — bone	0.34	0.66
brain — "CSF"	0.0003	0.9997

where I_0 = incident sound intensity
I_R = reflected " "
I_T = transmitted
and "CSF" = 0.154 mol. saline, equivalent to cerebrospinal fluid.

The reflection of ultrasound is determined by the general laws of radiation; thus the angle of reflection is equal to the angle of incidence. On oblique incidence from a liquid into a solid body the ultrasound may be totally reflected. For example, on passage from water to bone tissue (sound velocity for water: 1504, bone tissue: 3380 m/sec, cf. Table I) reflection may occur if the angle of incidence (β) exceeds 27° ($\sin \beta = \sin 90 \times 1504/3380$; $\beta = 27°$).

Calculations

When a sound wave penetrates a body containing interfaces between different media, part of the incident intensity is absorbed on traversing the material. Furthermore, reflection losses occur at the interfaces. If both the absorption coefficients and the acoustic impedances are known for the different media, the intensity of both the penetrating and the reflecting sound waves can be calculated in every point of the body (cf. Jeppsson 1961, p. 80).

The divergency angle $\rho = 1.22 \times \frac{\lambda}{D}$

where λ = the wave length and

D = the diameter of a circular radiating surface.

If the frequency and sound velocity are known the wave length can be calculated (frequency x wave length = sound velocity) The wave length is an approximate measure of the expected resolution at a frequency of 3 Mc/sec the wave length in water is approximately ½ mm. Consequently the uncertainty in the length determination, using ultrasound, is in principle at least of this order

When a wave motion traverses a medium some absorption always takes place. This absorption occurs as expressed in the formula

$$I = I_0 \times 10^{-\frac{s}{10} d}$$

where I_0 = the original intensity

s = the attenuation by absorption in dB per unit of length

d = the distance covered, and

I = the intensity when d has been traversed.

Intensity and amplitude (A) are related by the equation $I = A^2$ by taking the square roots the laws governing the intensity are applicable to amplitudes. Intensity is usually measured in watt/cm² Intensity divided by the sound velocity (v) gives the radiation pressure $P_{rad} = \frac{I}{v}$ N/cm² (Vigoreux 1966)

When an ultrasonic beam strikes the boundary separating two media with different acoustic impedances (Table I) some of the sound is transmitted and part is reflected at the interface

Table I *Sound velocity density and acoustic impedance for 0 154 mol. saline equivalent to cerebrospinal fluid ("CSF) brain tissue bone tissue and air of room temperature (according to Jeppsson 1961)*

Medium	sound velocity m/sec	density g/cm³	acoustic impedance g/cm² × sec
CSF"	1504	1.005	1.51×10^5
brain	1515	1 028	1.56×10^5
bone	3380	1.8	6.1×10^5
air	333	0.0012	4.0×10^1

The absorption losses in the skull (coefficient of absorption (a) at 2 Mc/sec is 4.5 dB/mm (Hüter 1952)) were calculated from the equation

$$\frac{I}{I_0} = 10^{-\frac{a}{10}t}$$

RESULT

Absorption losses $\frac{I}{I_0}$ at a frequency of	Skull thickness (t)	
	1 mm	3 mm
2 Mc/sec	$10^{-0.9}$	$10^{-2.7}$
4 Mc/sec	$10^{-1.8}$	$10^{-5.4}$

The absorption losses in the cerebral parenchyma (coefficient of absorption (a) at 2 Mc/sec is 1.5 dB/cm (Jeppsson 1961)) were calculated from the equation

$$\frac{I}{I_0} = 10^{-\frac{a}{10}d}$$

RESULT $\frac{I}{I_0} = 10^{-2.1}$ at 2 Mc/sec

$\frac{I}{I_0} = 10^{-4.2}$ at 4 Mc/sec

The term cerebral parenchyma includes here the entire distance between the internal surface of the skull and the lateral wall of the contralateral lateral ventricle (d, Fig. 1). Finally the reduction (R) at the interface between the cerebrospinal fluid and the cerebral parenchyma was taken from Table II.

$$\frac{I}{I_0} = R$$

RESULT $\frac{I}{I_0} = 10^{-1.9}$

Results

The results of the calculations are given in Figure 2, where it can be seen that

1) large reductions in intensity occur at the echo producing ventricular surface
2) at frequencies of 4 Mc/sec the absorption losses in the skull and cerebral parenchyma are relatively large.

Since it is the reflections, or echoes that are utilized in diagnostic examinations, it was considered of interest to determine the fraction of the incident intensity leaving the test object after a reflection

The following calculations were therefore performed. A child's head was considered, with a skull thickness (t) of 1 or 3 mm and a distance (d) of 7 cm between the internal surface of the skull and the lateral wall of the contralateral lateral ventricle (Fig 1) Ultrasound at frequencies of 2 Mc/sec or 4 Mc/sec was used in the calculations, the absorption coefficient being proportional to the frequency (Hüter 1952) The threshold for detectable echoes was found to be 10^{-10} of the incident intensity (Jeppsson 1961) for the same type of apparatus as used in this work

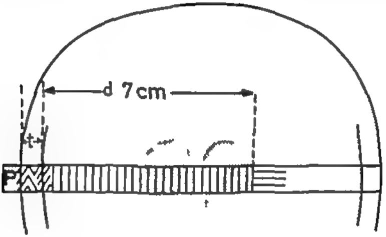

Figure 1 Schematic drawing of the head showing the beam pathway at an echoencephalographic examination.
Ultrasound with an intensity I_0 is transmitted through the probe (P) The ultrasound that is reflected at the lateral wall of the distal lateral ventricle, 7 cm from the internal surface of the skull, and returns to the probe (I), gives a so-called ventricle echo Before the echo can be recorded by the apparatus it is required that at least 10^{-10} of the transmitted ultrasound should return ($\frac{I}{I_0} \geq 10^{-10}$).
Losses of intensity occur by the absorption of ultrasound in the skull (t) and cerebral tissue (d) both on the outward and return passage and also due to reduction at the reflecting surface Other notation as in Fig. 2.

Reflection losses at the two surfaces of the skull (passed twice) were calculated using the transmission power (T) in Table II

$$\frac{I}{I_0} = T^4$$

$$\text{RESULT} \quad \frac{I}{I_0} = 10^{-0.7}$$

The absorption losses in the skull (coefficient of absorption (s) at 2 Mc/sec = 4.5 dB/mm (Hüter 1952)) were calculated from the equation

$$\frac{I}{I_0} = 10^{-\frac{s}{10} 2t}$$

RESULT:

Absorption losses $\frac{I}{I_0}$ at a frequency of	Skull thickness (t) 1 mm	Skull thickness (t) 3 mm
2 Mc/sec	$10^{-0.9}$	$10^{-2.7}$
4 Mc/sec	$10^{-1.8}$	$10^{-5.4}$

The absorption losses in the cerebral parenchyma (coefficient of absorption (s) at 2 Mc/sec = 1.5 dB/cm (Jeppson 1961)) were calculated from the equation

$$\frac{I}{I_0} = 10^{-\frac{s}{10} 2d}$$

RESULT: $\frac{I}{I_0} = 10^{-2.1}$ at 2 Mc/sec

$\frac{I}{I_0} = 10^{-4.2}$ at 4 Mc/sec

The term cerebral parenchyma includes here the entire distance between the internal surface of the skull and the lateral wall of the contralateral lateral ventricle (d, Fig 1) Finally the reduction (R) at the interface between the cerebrospinal fluid and the cerebral parenchyma was taken from Table II

$$\frac{I}{I_0} = R$$

RESULT $\frac{I}{I_0} = 10^{-2.9}$

Results

The results of the calculations are given in Figure 4, where it can be seen that

1) large reductions in intensity occur at the echo producing ventricular surface;
2) at frequencies of 4 Mc/sec the absorption losses in the skull and cerebral parenchyma are relatively large

3) the absorption losses increase greatly with increasing skull thickness

4) at a skull thickness of 3 mm, echoes from the distal ventric surface can be recorded with ultrasonic frequencies of 2 Mc/ c/sec

5) because of the relatively large reduction in ption in the cerebral tissues it should be possible wall of the proximal ventricle w th where the skull thickness is

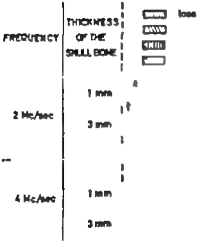

Figure 2 The

sound is detected b

surface (Fig 1). detectable frequency level (thin skulls.

Discussion of

The coeffici data in the lit newborn babies be lower both a lower calciu losses are prob indicated in Fig cular surface wi the differences cerebral parench be recorded.

As with wave movements in general, ultrasonic waves transport energy

The ultrasound used for diagnostic purposes is emitted in short intense pulses separated by resting periods, which gives a low mean intensity

In the reflectoscope used here, the ultrasonic beam has a frequency of 2—4 Mc/sec and a mean intensity of 2.5×10^{-4} watt/cm² which is far below the limit for harmful effects damage was observed in animal tissue experiments at 3.25 watt/cm (Barth & Bülow 1949) before any trauma occurs, the skull has to be damaged, and before this happens skin lesions are manifest, and long before this, pain is experienced (Hüter 1954) a routine echoencephalographic examination may at most give a local increase in temperature of 0 1 C (Jeppsson 1961)

Cavitation will not occur in these frequency and intensity ranges (cf Baldes et al 1958)

In infants, especially newborn babies, the ultrasonic energy penetrates more easily into the cerebral parenchyma than in adults, therefore it is necessary to make sure that even the short intense pulses used in echoencephalography do not produce other harmful effects than heating.

The pulses used have a peak intensity of about 2.5 watt/cm² lasting for about 5 μsec, followed by a resting period of about 5000 μsec (Jeppsson 1961)

Calculations

1 *Thermal effects*

Using the value given by Jeppsson (1961) for temperature increase during a routine examination (3 minutes), i.e. 0 1 C, disregarding any transport of heat from the tissue due to blood circulation, etc., the following calculations were performed.

If the maximum permissible temperature increase is 3 degrees (37°—40 C) the maximum time (t_{max}) for investigation is

$$t_{max} = \frac{3}{0.1} \times 3 = 90 \text{ minutes.}$$

Thus, if an echoencephalographic examination were to take 9 minutes, instead of the 3 minutes in Jeppsson's calculations, the mean intensity could be raised 10 times, to

$$2.5 \times 10^{-4} \times 10 = 25 \times 10^{-4} \text{ watt/cm}^2$$

3) the absorption losses increase greatly with increasing skull thickness

4) at a skull thickness of 3 mm echoes from the distal ventricular surface can be recorded with ultrasonic frequencies of 2 Mc/sec, but not 4 Mc/sec

5) because of the relatively large reduction in intensity due to absorption in the cerebral tissues it should be possible to record echoes from the lateral wall of the proximal ventricle with frequencies of 2 Mc/sec even in cases where the skull thickness is somewhat greater than 3 mm.

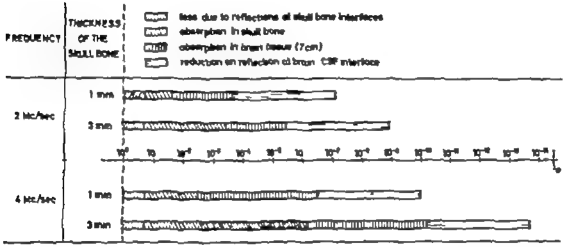

Figure 2 The figure shows the extent to which the intensity (I_0) of the transmitted ultrasound is detected by the echoencephalograph $\left(\frac{I}{I_0}\right)$ after reflection against the distal ventricular surface (Fig 1) The bars give the distribution of the intensity losses. The threshold for detectable echoes is 10^{-9} to 10^{-10} of the incident intensity It can be seen that the higher frequency level (4 Mc/sec) which makes the beam more parallel, can only be used with very thin skulls.

Discussion of the calculations

The coefficients of absorption for the above calculations were obtained from data in the literature based on measurements mainly from adult tissue. For newborn babies and infants the coefficients of absorption may be expected to be lower both for the skull and the cerebral tissue, because of for example, a lower calcium density and lower degree of myelinization The absorption losses are probably lower therefore, for newborn babies and infants than is indicated in Figure 2. On the other hand the reflection capacity of the ventricular surface will be lower with decreased density of the cerebral tissue. When the differences in acoustic impedance between the cerebrospinal fluid and cerebral parenchyma are sufficiently small no ventricular echoes at all can be recorded.

intensity of 2.5 × 10^{-4} watt/cm² or alternatively to increase this intensity 10 times during a 9-minute examination, before pain or any harmful thermal effects will occur·

2. at the high peak intensity (2.5 watt/cm²) repeatedly occurring in the ultrasonic beam, the maximum radiation pressure on, for example, a cell membrane is still negligibly small even under the most unfavourable circumstances, such as total reflection, and will not exceed 3 mm H_2O

3 the kinetic energy of a molecule vibrating in the ultrasonic field is at most 4 × 10^{-24} Ws or 10^{-4} eV this energy is small compared to the kinetic energy of the molecules due to their thermal movements, i.e. 4.3 × 10^{-21} Ws it is also small compared to the bonding energy in the molecule (of the order 1 eV) the quanta of vibrational energy of the molecules (of the order of 10^{-1} eV) and the quanta of rotational energy of the molecules (of the order of 10^{-2} eV)

the acceleration force acting upon an atom in a molecule vibrating at body temperature is more than 10^{13} g this force is shown to be 10^{10} times greater than the acceleration force due to the ultrasonic field, although this latter force has been shown to be as great as 10^3 g.

III. DISCUSSION

The property of ultrasound that makes it particularly suitable for distance measurement is the near parallelism of the beam, which can be propagated through human tissues. Some absorption takes place in the tissues with increasing frequency the absorption increases, but so also does the parallelism of the beam. Frequencies of about 1—4 Mc/sec give sufficiently parallel beams without too much absorption. Ultrasound is reflected at interfaces between tissue structures with different acoustic impedances. The reflections, or echoes, are used for diagnostic purposes. The time taken for the ultrasound to traverse a given distance in a homogeneous medium is directly proportional to the distance.

In order that the reflected ultrasound should return to the same point from which it is transmitted, it must be directed normally to the reflecting surface. When passing in oblique incidence from a soft tissue into bone, ultrasound may be totally reflected even if the angle of incidence exceeds only about 27 (p 15).

At an interface between a solid and a gas the main part of the incident sound intensity will be reflected, due to large differences between the acoustic impedances thus, gas in the path of the beam would cause practically total reflection.

The calculations described on pages 15—18 show that with a sufficiently thin skull it is possible to record echoes from the interface between cerebrospinal fluid and cerebral parenchyma with ultrasonic frequencies of 4 Mc/sec. It is

2 *Mechanical effects*

Using the relation radiation pressure $P_{rad} = \frac{I}{v}$ (p 14) and assuming total reflectance, the pressure on a reflecting surface may be calculated at the peak intensity used (2.5 watt/cm²) and a sound velocity of 1500 m/sec

$$P_{rad} = 2 \times \frac{2.5\ \text{watt/cm}^2}{1500\ \text{m/sec}} \approx \frac{5 \times 10^4\ \text{N m/sec m}^2}{1500\ \text{m/sec}} = 33\ \text{N/m}^2$$

the pressure of 33 N/m² is approximately equal to 3 mm H_2O

3 *Molecular effects*

The thermal energy which corresponds to the heat movement of the molecules is determined by kT where k is the Boltzmann constant ($1\ 4 \times 10^{-23}$ Ws/degree) and T the absolute temperature. At 37°C this energy is equal to

$1\ 4 \times 10^{-23} \times (273 + 37) = 4.3 \times 10^{-21}$ Ws.

At ultrasound frequencies of 1 Mc/sec and 4 watt/cm² a particle in biological tissue oscillating in the ultrasonic field will have a maximal speed of 0.224 m/sec (Hertz 1962) A molecule with a molecular weight of 100 000 i e. 1.7×10^{-22} kg will have a corresponding kinetic energy (E_{kin}) of

$$E_{kin} = \frac{mv^2}{2} = \frac{1.7 \times 10^{-22}\ (0.224)^2}{2} = 4 \times 10^{-24}\ \text{Ws} \approx 10^{-4}\ \text{eV}$$

The quotient between the thermal energy of molecules and the kinetic energy due to oscillations in the ultrasonic field is thus

$$\frac{4.3 \times 10^{-21}}{4 \times 10^{-24}} \approx 1000$$

It has also been shown (Hertz 1962) that the elementary particles in the ultrasonic beam undergo accelerations to the order of 10^3 g (acceleration = amplitude × (angular frequency)²) Using human standards, this figure seems to be *very high but the comparison must be made with accelerations* on an elementary particle level The acceleration force exerted on an atom in a molecule vibrating at absolute zero with an amplitude of 0 1 Å and a frequency of 10^{13} c/sec is

$0\ 1 \times 10^{-10} \times (2\pi \times 10^{13})^2 \approx 4 \times 10^{16}$ m/sec² $\approx 10^{15}$ g

or 10^{10} times greater than the acceleration caused by the ultrasound

Results and discussion

Under the above assumptions the calculations show that

1 it is possible to examine a patient continuously for 90 minutes, at a mean

intensity of 2.5×10^{-4} watt/cm² or alternatively to increase this intensity 10 times during a 9-minute examination, before pain or any harmful thermal effects will occur;

2. at the high peak intensity (2.5 watt/cm²) repeatedly occurring in the ultrasonic beam, the maximum radiation pressure on, for example, a cell membrane is still negligibly small, even under the most unfavourable circumstances, such as total reflection, and will not exceed 3 mm H_2O

3. the kinetic energy of a molecule vibrating in the ultrasonic field is at most 4×10^{-44} Ws or 10^{-6} eV; this energy is small compared to the kinetic energy of the molecules due to their thermal movements, i.e. 4.3×10^{-21} Ws; it is also small compared to the bonding energy in the molecule (of the order 1 eV) the quanta of vibrational energy of the molecules (of the order of 10^{-1} eV) and the quanta of rotational energy of the molecules (of the order of 10^{-4} eV)

the acceleration force acting upon an atom in a molecule vibrating at body temperature is more than 10^{15} g this force is shown to be 10^{10} times greater than the acceleration force due to the ultrasonic field, although this latter force has been shown to be as great as 10^{5} g.

III DISCUSSION

The property of ultrasound that makes it particularly suitable for distance measurement is the near parallelism of the beam, which can be propagated through human tissues. Some absorption takes place in the tissues with increasing frequency the absorption increases, but so also does the parallelism of the beam. Frequencies of about 1—4 Mc/sec give sufficiently parallel beams without too much absorption. Ultrasound is reflected at interfaces between tissue structures with different acoustic impedances. The reflections, or echoes, are used for diagnostic purposes. The time taken for the ultrasound to traverse a given distance in a homogeneous medium is directly proportional to the distance.

In order that the reflected ultrasound should return to the same point from which it is transmitted, it must be directed normally to the reflecting surface. When passing in oblique incidence from a soft tissue into bone, ultrasound may be totally reflected even if the angle of incidence exceeds only about 27° (p 15)

At an interface between a solid and a gas the main part of the incident sound intensity will be reflected, due to large differences between the acoustic impedances thus, gas in the path of the beam would cause practically total reflection.

The calculations described on pages 15—18 show that with a sufficiently thin skull it is possible to record echoes from the interface between cerebrospinal fluid and cerebral parenchyma with ultrasonic frequencies of 4 Mc/sec. It is

2 Mechanical effects

Using the relation radiation pressure $P_{rad} = \frac{I}{v}$ (p 14) and assuming total reflectance, the pressure on a reflecting surface may be calculated at the peak intensity used (2.5 watt/cm²) and a sound velocity of 1500 m/sec

$$P_{rad} = 2 \times \frac{2.5 \text{ watt/cm}^2}{1500 \text{ m/sec}} = \frac{5 \times 10^4 \text{ N m/sec m}^2}{1500 \text{ m/sec}} = 33 \text{ N/m}^2$$

the pressure of 33 N/m² is approximately equal to 3 mm H_2O

3 Molecular effects

The thermal energy which corresponds to the heat movement of the molecules is determined by kT where k is the Boltzmann constant (1.4×10^{-23} Ws/degree) and T the absolute temperature. At 37°C this energy is equal to

$1.4 \times 10^{-23} \times (273 + 37) = 4.3 \times 10^{-21}$ Ws

At ultrasound frequencies of 1 Mc/sec and 4 watt/cm² a particle in biological tissue oscillating in the ultrasonic field will have a maximal speed of 0.224 m/sec (Hertz 1962) A molecule with a molecular weight of 100 000 i.e. 1.7×10^{-22} kg will have a corresponding kinetic energy (E_{kin}) of

$$E_{kin} = \frac{mv^2}{2} = \frac{1.7 \times 10^{-22} (0.224)^2}{2} = 4 \times 10^{-24} \text{ Ws} \approx 10^{-4} \text{ eV}$$

The quotient between the thermal energy of molecules and the kinetic energy due to oscillations in the ultrasonic field is thus

$$\frac{4.3 \times 10^{-21}}{4 \times 10^{-24}} \approx 1000$$

It has also been shown (Hertz 1962) that the elementary particles in the ultrasonic beam undergo accelerations to the order of 10^5 g (acceleration = amplitude × (angular frequency)²) Using human standards, this figure seems to be very high but the comparison must be made with accelerations on an elementary particle level. The acceleration force exerted on an atom in a molecule vibrating at absolute zero with an amplitude of 0.1 Å and a frequency of 10^{13} c/sec is

$0.1 \times 10^{-10} \times (2\pi \times 10^{13})^2 \approx 4 \times 10^{16}$ m/sec² $\approx 10^{15}$ g

or 10^{10} times greater than the acceleration caused by the ultrasound.

Results and discussion

Under the above assumptions the calculations show that

1 it is possible to examine a patient continuously for 90 minutes, at a mean

1) echoes from the interface between cerebrospinal fluid and cerebral parenchyma can be recorded with ultrasound at frequencies of 4 Mc/sec, when the skull bone is about 1 mm thick,

2) echoes from the interface between cerebrospinal fluid and cerebral parenchyma can be recorded with ultrasound at frequencies of 2 Mc/sec, when the skull is about 3 mm thick, and

3) the energy transferred to the tissues during a diagnostic ultrasonic echo examination (A-scan) is considerably below the level at which harmful effects may occur

also seen that the absorption losses increase greatly with increasing cranial thickness Similar calculations were performed by Jeppsson (1961) who showed that in adults reflection occurs against more or less calcified intracranial structures, such as, for example, the pineal body even very minor calcium deposits, which are not visible roentgenologically constitute a good medium of reflection of ultrasound with a minimal reduction of intensity In infants, on the other hand, where the skull is thin *reflection is detected from the interface between the* cerebrospinal fluid and cerebral parenchyma. At such ages where firstly the skull has become so thick that reflection from the interface between cerebrospinal fluid and cerebral praenchyma can no longer be recorded and secondly the intracranial calcifications have not had time to progress to such a degree that the reflection losses are sufficiently small it may be difficult or sometimes impossible to record any echoes at all from intracranial structures (see Jeppsson 1961 *Graph 9*)

It has been shown that a routine investigation using a mean effect of 2.5×10^{-4} W/cm² *may give an increase in temperature* of about 0 1°C, disregarding any transport of energy from the tissue (Jeppsson 1961) while damage has been observed with the use of 3.25 W/cm² (Barth & Bülow 1949) injurious effects are thought to be due to increased temperature, and the calculations on page 20 confirm this theory Only when the ultrasonic motions of the molecules have been randomized i e. transformed into heat, will the molecules obtain kinetic energies high enough to produce harmful effects

For echoencephalography *ultrasound at frequencies of 2—4 Mc/sec, and with* mean intensities of 2.5×10^{-4} watt/cm² is used such intensities cause no sensation of pain or biological trauma On the other hand ultrasound of higher intensities and with continuous or focused radiation can give rise to tissue damage and at lower frequencies the risk of cavitation will increase.

The data concerning absorption and damage, cited above have been obtained from adult tissues Because of the wide safety margins shown to exist, the ultrasonic echo *examination method is safe, even applied to infants, although in*fantile tissue is more vulnerable. However more data concerning infantile tissue would be valuable in order to enable more elaborate calculations for echographic examinations in newborn babies infants and children of different ages.

IV SUMMARY

A short review of some physical properties of ultrasound is presented, and their *importance for* echoencephalographic examinations is discussed.

Calculations made on the basis of data concerning adult tissues, given by other authors, show that

It consists of a measuring unit (A) with a built in oscilloscope (hidden by the camera adapter (B)) and can be fitted with interchangeable probes (C) and also a Polaroid Land Camera (D) for photographing the oscillogram

Figure 4 shows a block diagram of the system High frequency alternating current from the high frequency generator (see Fig 4.A) is converted to ultra sound by a piezo-electric barium titanate crystal enclosed in the probe (Fig 4-C) The crystal is also able to convert ultrasound to electrical impulses. (A piezo-electric crystal has the property of transforming applied mechanical vibrations (sound) into periodic electrical potential differences between the surfaces of the crystal conversely periodic electrical voltages give rise to mechanical vibrations. These are strongest at the resonance frequencies of the crystal)

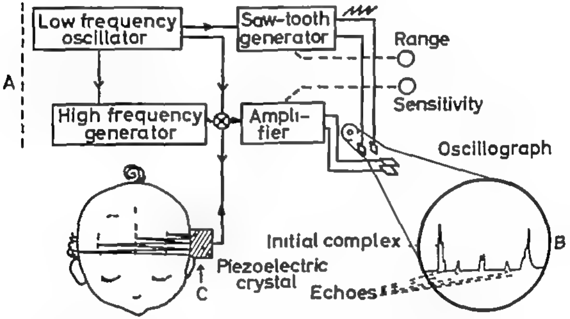

Figure 4 Block diagram of the measuring unit (A) and the picture in the oscilloscope (B) in an echoencephalographic examination of a child with hydrocephalus, where the probe (C) has been applied to the temporal region of the head.

The low frequency generator (see Fig 4.A) functions as a pacemaker and gives pulses with a frequency of 200—250 cycles per second. These pulses influence

1) the high frequency oscillator which together with the crystal gives a transient pulse train lasting about 5×10^{-6} seconds and at a frequency usually between 2 and 4×10^{6} c/sec, i e. 10—20 oscillations the high frequency pulses are heavily damped and decay after about 5 μsec. After this the crystal functions

as a microphone, until the next high frequency pulse train is emitted, i. e. after about 5000 μsec

2) the saw tooth power generator which regulates the X plates of the oscilloscope (Fig. 4-B), giving a horizontal sweep at a frequency of 200—250 cycles per second

3) the amplifier which regulates the input of the Y-plates of the oscilloscope. The low frequency pulses are of such a form that the amplifier is blocked during the period of ultrasound emission. This block is not total, however The strong signal transmitted can be visualized as a complex of deflections in the oscilloscope. This is called the initial complex, and its beginning represents the zero point on the X axis (time-axis).

When the block is removed the amplification is not constant but increases with time. This tends to compensate for the greater damping of those echoes that are returning from deeply situated structures, and thus compensates for their longer absorption distance through the medium

Ultrasound emitted from the probe (Fig. 4-C) strikes a reflecting surface perpendicular to the beam, and returns to the probe, where it is converted by the piezo-electric crystal to electrical impulses, which are then visualized in the oscilloscope as deflections the distance between the initial complex and the upward limbs of these deflections is a measure of the time taken for the ultrasound to pass to and return from the structure which gives the echo If this time (t) and the speed of sound in the medium (v) are known, the distance (d) to the reflecting interface can be calculated ($d = \frac{1}{2} \cdot v \cdot t$). The distance between the beginning of the initial complex and the upward limb of the echo deflection is, *therefore*, proportional to the distance from the site of the probe on the surface of the head to the echo-producing structure. The proportionality factor depends on the setting of the controls for range and scale (Figure 3.(6) and (5))

Probes with a frequency of 4 Mc/sec, and a diameter of 10 mm were used for the examination of infants, and Mc/sec and 10 or 24 mm, respectively for older children.

The probe is constructed so that it can function both as transmitter and receiver (transceiver) for the echo examination. For the midline control examination by the transmission method (Vlieger & Ridder 1959 Lithander 1960, Jeppsson 1961), one probe was used as transmitter and another as receiver by means of a switch (Fig. 3 13) rapid variation between the different methods of examination was possible

Two special test bodies, corresponding to 25 mm and 2.5 mm tissue, respectively are supplied for calibration of the apparatus.

For further details of the coupling system and the apparatus in general, reference should be made to the manufacturer s instructions.

It consists of a measuring unit (A) with a built in oscilloscope (hidden by the camera adapter (B)) and can be fitted with interchangeable probes (C) and also a Polaroid Land Camera (D) for photographing the oscillogram

Figure 4 shows a block diagram of the system High frequency alternating current from the high frequency generator (see Fig 4.A) is converted to ultra sound by a piezo-electric barium titanate crystal enclosed in the probe (Fig. 4-C) The crystal is also able to convert ultrasound to electrical impulses. (A piezo-electric crystal has the property of transforming applied mechanical vibrations (sound) into periodic electrical potential differences between the surfaces of the crystal conversely periodic electrical voltages give rise to mechanical vibrations These are strongest at the resonance frequencies of the crystal)

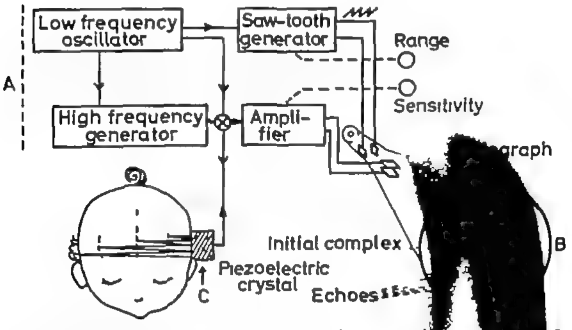

Figure 4 Block diagram of the measuring it (A) and the p cture in th [illegible] echoencephalographic examination of a child with hydrocephalus, where [illegible] applied to the temporal region of the head.

The low frequency generator (see Fig 4.A) functions as gives pulses with a frequency of 200—250 cycles per secon fluence:

1) the high frequency oscillator which, together with the cry sient pulse train lasting about 5×10^{-6} seconds and at a freq tween 2 and 4×10^{6} c/sec, i e. 10—20 oscillations the high fre heavily damped and decay after about 5 μsec. After this the

as a microphone, until the next high frequency pulse train is emitted, i. e. after about 5000 µsec.

2) the saw-tooth power generator which regulates the X plates of the oscilloscope (Fig. 4.B), giving a horizontal sweep at a frequency of 200—250 cycles per second.

3) the amplifier which regulates the input of the Y plates of the oscilloscope. The low frequency pulses are of such a form that the amplifier is blocked during the period of ultrasound emission. This block is not total however. The strong signal transmitted can be visualized as a complex of deflections in the oscilloscope. This is called the initial complex, and its beginning represents the zero point on the X axis (time-axis).

When the block is removed the amplification is not constant but increases with time. This tends to compensate for the greater damping of those echoes that are returning from deeply situated structures, and thus compensates for their longer absorption distance through the medium.

Ultrasound emitted from the probe (Fig. 4·C) strikes a reflecting surface perpendicular to the beam, and returns to the probe, where it is converted by the piezo-electric crystal to electrical impulses, which are then visualized in the oscilloscope as deflections. the distance between the initial complex and the upward limbs of these deflections is a measure of the time taken for the ultrasound to pass to and return from the structure which gives the echo. If this time (t) and the speed of sound in the medium (v) are known, the distance (d) to the reflecting interface can be calculated ($d = \frac{1}{2} \cdot v \cdot t$). The distance between the beginning of the initial complex and the upward limb of the echo deflection is, therefore, proportional to the distance from the site of the probe on the surface of the head to the echo-producing structure. The proportionality factor depends on the setting of the controls for range and scale (Figure 3.(6) and (5)).

Probes with a frequency of 4 Mc/sec, and a diameter of 10 mm were used for the examination of infants, and 2 Mc/sec and 10 or 24 mm, respectively for older children.

The probe is constructed so that it can function both as transmitter and receiver ("transceiver") for the echo examination. For the midline control examination by the transmission method (Vlieger & Ridder 1959, Lithander 1960, Jeppsson 1961) one probe was used as transmitter and another as receiver: by means of a switch (Fig. 3.13) rapid variation between the different methods of examination was possible.

Two special test bodies, corresponding to 25 mm and 2.5 mm tissue, respectively are supplied for calibration of the apparatus.

For further details of the coupling system and the apparatus in general, reference should be made to the manufacturer's instructions.

The apparatus was calibrated and its linearity tested

The *degree of proportionality between the time (X) axis of the oscilloscope and the distances measured* was tested using multiple reflections in the 2.5 mm tissue standard, and the deviation from *linearity was in no place greater than the degree of uncertainty in the individual values,* e g ± 0.3 mm.

In order to determine *whether the horizontal scale remained unchanged when the oscilloscopic tracing was moved vertically* recordings in the four possible oscilloscopic positions were made on one and the same photograph the distance from the beginning of the initial complex to the upward limb of the echo deflection obtained was found to be exactly the same in all positions.

To determine the *numerical relationship between the length of the tissue investigated and the distance in the oscilloscope* (a) *and the distance on the photographic recordings* (b) from the initial complex to the echo deflection for different settings of the apparatus, the following test was performed

Table III *Values obtained from echorecordings from 25 mm tissue standard with the apparatus set at different ranges The setting of the apparatus in other respects is described in the text*

Range according to the apparatus	Measured tissue distance in mm	No. of scale divisions in the oscilloscope (a)	No. of mm on the photograph (b)
100 × 0.5 mm	25	24	40
100 × 1 mm	25	12	20
100 × 2 mm	25	6	10
250 × 0.5 mm	25	10	16
250 × 1 mm	25	5	8
250 × 2 mm	25	2.5	4

A tissue standard corresponding to 25 mm tissue was studied, a probe of 4 Mc/sec and 10 mm diameter being used. Using the horizontal position control, the beginning of the initial complex was placed at the left vertical line in the coordinate grid of the oscilloscope. With the range set at 100 × 0.5 mm, the first echo from the tissue standard was made to coincide with the right margin of the coordinate grid by means of the scale control.

Recordings were then made using all range combinations (Table III)

The distances between the beginning of the initial complex and the different deflections were measured.

The values obtained are given in Table III which shows that the ranges given on the apparatus were in good agreement with the true conditions, since the previous test had proved the linearity of the apparatus.

Thus, it was shown that the apparatus was linear and that its range was in good agreement with the true conditions.

Comments

Provided that the sweep of the apparatus is not altered, calculations can be made from the values in Table III to determine firstly which range is most suitable for the examination of a given length of tissue, and secondly the length of tissue that corresponds to a distance obtained on the photograph. To simplify such calculations in practical work, the following table has been found to be of value (Table IV).

Table IV *Calculations for practical use of the counterparts of different stretches of tissue on the photographic recordings at different measurement ranges of the apparatus as seen in the table the range 100 × 1 mm is most suitable for infants with a small cranial diameter while the range 250 × 0.5 is to be preferred in older children and adults.*

Range according to the apparatus	8 cm on the photograph corresponds to tissue distance of	1 mm on the photograph corresponds to tissue distance of
100 × 0.5 mm	5 cm	0.6 mm
100 × 1 mm	10 cm	1.2 mm
100 × 2 mm	20 cm	2.5 mm
250 × 0.5 mm	12.5 cm	1.6 mm
250 × 1 mm	25 cm	3.1 mm
250 × 2 mm	50 cm	6.2 mm

The photographic recording measured 10 cm (X axis) × 8 cm (Y-axis). It can be seen from Table IV that a range of 100 × 1 mm is most suitable for examinations of infants with a cranial diameter of about 10 cm, while a range of 250 × 0.5 mm is preferable in children with larger heads, and adults. At a range of 100 × 1 mm, 1 mm tissue corresponds to 0.8 mm on the photographic recording and 1 mm on the photograph corresponds to 1.25 mm tissue.

Most other commercially available apparatuses for echoencephalography follow the same principles as those used in this work for details of each individual type of apparatus, reference should be made to the manufacturer's manual of instructions.

II. PROCEDURE

Preparations

For the examination the patient lay in the supine position with the nose pointing straight up towards the ceiling (Fig. 5) Usually the child had recently

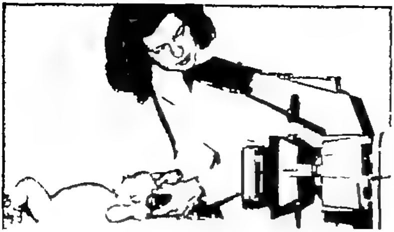

Figure 5 During the examination the patient lay symmetrically in the supine position. The photograph was taken during scanning with the probe held immediately posterior to the test point.

slept and been fed and he was accompanied by his own nurse and if necessary was given a pacifier to suck No sedation was ever required.

Contact media

Liquid paraffin was used as a contact medium between the surface of the probe and the head which was not shaved before the examination

Test point

The probe was, as a rule, held 2—3 cm above and 1—3 cm anterior to the external auditory meatus (test point Tp Fig 6) The probe was directed towards the corresponding point on the opposite side of the head.

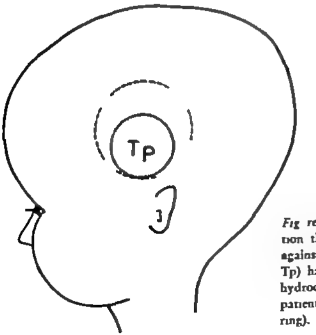

Fig re 6 In an echoventriculographic examination the central point of the site on the head against which the probe is placed (test point, Tp) has to be sought with w der region in hydrocephalic pat ents (dotted ring) than patients with normal cra ial d ameters (whol ring).

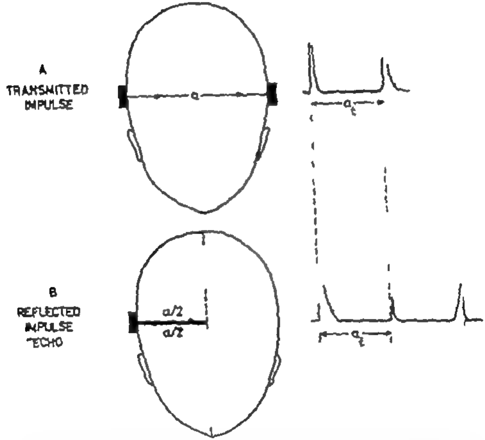
Midline control

The examination was begun with a midline control (see p. 29) whereby ultrasound was transmitted by one probe and detected by another placed congruently on the opposite side of the head (Fig. 7) the surfaces of the two probes were held parallel. The oscillogram at the midline control examination was photographed.



F g re 7 Midline control The time taken for ltrasound to pass from the one probe (black) to the other ( ) by the transmission method (A) is equal to that taken for it to pass from one probe to he geometrical midline (dotted) and back again to the same probe, as in the echo method (B). The distanc measure of the same time on the oscilloscope screen.

Echo examination

The echo examination was performed from both the right and left sides, from the same points at which the probes were placed for the midline control exami

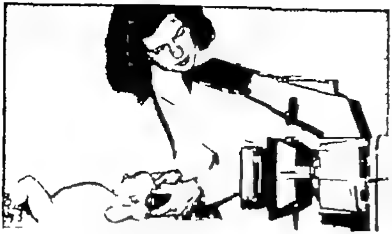


Figure 5 During the examination the patient lay symmetrically in the supine position. The photograph was taken during scanning with the probe held immediately posterior to the test point.

slept and been fed, and he was accompanied by his own nurse and if necessary was given a pacifier to suck. No sedation was ever required.

Contact media

Liquid paraffin was used as a contact medium between the surface of the probe and the head which was not shaved before the examination.

Test point

The probe was, as a rule, held 2—3 cm above and 1—3 cm anterior to the external auditory meatus (test point Tp, Fig. 6). The probe was directed towards the corresponding point on the opposite side of the head.

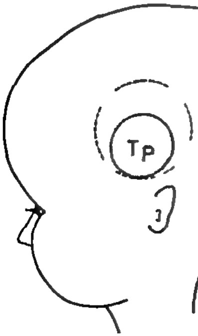

Figure 6. In an echoventriculographic examination the central point of the site on the head against which the probe is placed (test point, Tp) has to be sought within a wider region in hydrocephalic patients (dotted ring) than in patients with normal cranial diameters (whole ring).

Midline control

The examination was begun with a midline control (see p. 29), whereby ultrasound was transmitted by one probe and detected by another placed congruently on the opposite side of the head (Fig. 7) the surfaces of the two probes were held parallel. The oscillogram at the midline control examination was photographed.

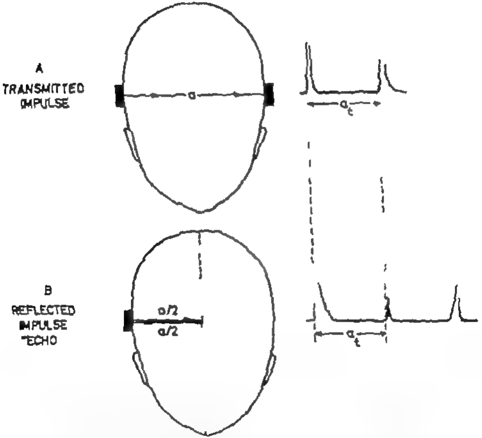

Figure Midline control. The time taken for ultrasound to pass from the one probe (black) to the other ( ) by the transmission method (A) is equal to that taken for it to pass from one probe to the geometrical midline (dotted) and back again to the same probe, as in the echo method (B). slept and been fed, and he was accompanied by his own nurse and if necessary was given a pacifier to suck No sedation was ever required

Contact media

Liquid paraffin was used as a contact medium between the surface of the probe and the head which was not shaved before the examination.

Test point

The probe was, as a rule, held 2—3 cm above and 1—3 cm anterior to the external auditory meatus (test point Tp Fig 6) The probe was directed towards the corresponding point on the opposite side of the head

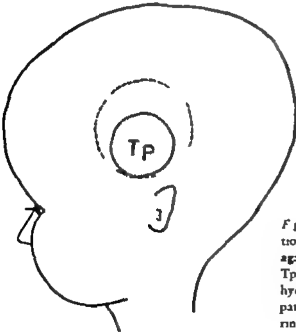

Figure 6 In an echoventriculographic examination the central point of the site on the head *against which the probe is placed* (test point, Tp) has to be sought within a wider region in hydrocephalic patients (dotted ring) than in patients with normal cranial diameters (whole ring)

Midline control

The examination was begun with a midline control (see p 29) whereby ultrasound was transmitted by one probe and detected by another placed congruently on the opposite side of the head (Fig. 7) the surfaces of the two probes were held parallel. The oscillogram at the midline control examination was photographed.

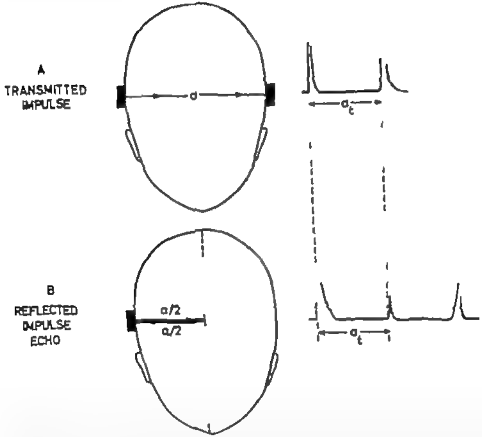

Figure 7 Midline control. The time taken for ultrasound to pass from the one probe (black) to the other ( ) by the transmission method (A) is equal to that taken for it to pass from one probe to the geometrical midline (dotted) and back again to the same probe, as in the echo method (B). The distance a_t is *measure of the same time on the oscilloscope screen.*

Echo examination

The echo examination was performed from both the right and left sides, from the same points at which the probes were placed for the midline control exami

nation At the echo examination the oscillogram was followed while the probe was moved slightly against the surface of the head and the gain control of the apparatus was manoeuvred The bottom echo midline echo echo-free zones and lateral ventricle echoes were identified on the oscilloscope screen When the midline echo and the distal lateral ventricle echo appeared to rise at their steepest angles from the time axis, the oscillogram was photographed

Lateral ventricle echo

The lateral ventricle echo was defined as that echo which delimited laterally an echo-free zone, which in turn was divided medially by the midline echo a check was made that the echo-free zone remained free of echoes even at maximal amplification In cases where the midline echo and lateral ventricle echoes could not be identified simultaneously from the position used for the *midline control examination* a new *midline control recording* was made from the site at which these echoes could be detected

"Scanning"

After each echo examination as described above the tracing in the oscilloscope was observed while the probe was being moved along the sides of the head and also while the probe was held in a fronto-occipital and occipito-frontal direction This part of the investigation was called "scanning

On scanning

1) the *identity of the midline echo* was verified a midline echo usually pulsating can be recorded over a considerably larger area of the head in children than in adults (Jeppson 1960 Lithander 1961)

2) any *asymmetries anterior or posterior to the test point* were recorded photographically

3) *the width of the midline echo* was checked while the probe was moved 1—2 cm forwards and downwards from the test point in cases where the configuration and/or the width of the midline echo was then found to be altered, a fourth recording was photographed corresponding *to the region of projection of the third ventricle*

4) *the extent of an echo-free zone from the ventricular system was noted* if its breadth was not considered to correspond to that of a harmonically dilated ventricular system the deviating oscillogram was photographed

5) *any echo-free zones suspected to be of other origin than the ventricular system* which aroused suspicion of porencephaly or cyst of the fourth ventricle, for example were recorded photographically

6) any *atypical repeatedly recurring echoes* which aroused suspicion of for example a cyst wall or tumorous calcification were recorded photographically

Other recordings

When photographic recordings were made as in points 2, 4 5 and 6 a midline control determination was also made, when possible, between the congruent points on each side of the head, from which the echoes had been recorded.

In echo examinations performed in a fronto-occipital and/or occipito-frontal direction, the probe was held on the right and left side of the forehead and/or the occipital region, respectively for midline control determinations in the longitudinal plane the probes were held in the centre of the forehead and centrally over the most prominent part of the neck, thus corresponding to the largest longitudinal cranial diameter In all cases where such extra recordings were made, the position and direction of the probe at the examination was denoted by arrows on a sketch of the head, drawn for each individual patient.

III. ECHOENCEPHALOGRAM AND ECHOVENTRICULOGRAM (EVG)

Definitions

Echoencephalogram

By echoencephalogram is meant one single reflection pattern recording (Leksell 1955 56) Depending on the thickness of the skull and the position of the probe an echoencephalogram consists of deflections (echoes) due to the reflection of the ultrasound *from the skull and different intracranial structures.*

Echoventriculogram (EVG)

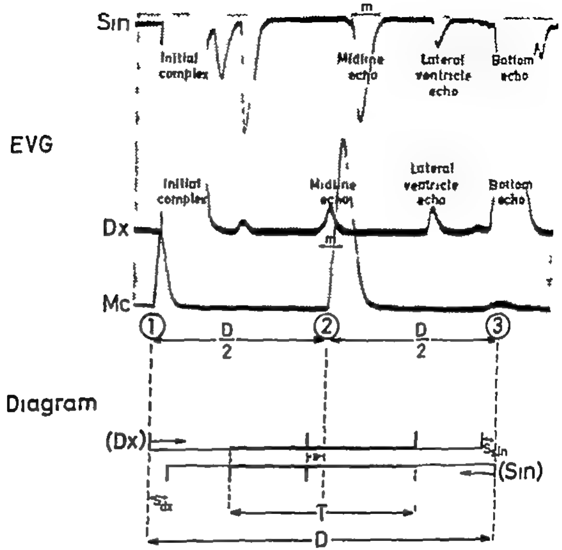
By echoventriculogram (EVG) is meant a photographic recording of a midline control between the right and left test points together with echoencephalograms showing the midline echo (see 3) p. 34) bottom echo and distal lateral ventricle echo from the right and left test points.

Graphical representation and index calculations of EVG

In the following the methods of graphical representation and index calculations are described, and the reader is referred to Figure 8.

The grey field in Figure 8 shows a model EVG, in which Mc at the bottom denotes the midline control recording, Dx an echoencephalogram from the right test point, and Sin an echoencephalogram from the left test point.

Each recording begins with the *initial* complex the measurements are made from the beginning of this complex (the thin upward limb at the end of the first straight part on the time axis) to the upward limbs of deflections in the different recordings.



Indices

Lateral venticular index $= I = T/D$

Midline index $= I_m = m/D$

Midline deviation index $= I_x = x/D$

Superficial structure index $= I_s = s/D$

Figure 8 An echoventriculogram (EVG) within the gray field, where Mc represents the midline control Dx an echoencephalogram from the right and Sin one from the left test point. The graphical representation and index calculations are explained in the text.

Midline control recording (Mc)

From the initial complex and the upward limb of the single deflection in Mc (EVG, Fig. 8) vertical parallel dotted lines are drawn downwards, marked 1 and 2 the distance between 1 and 2 is called midline control distance and marked $\frac{D}{2}$ The double midline control distance is also marked with a vertical line (3) parallel with the vertical lines 1 and 2. The double midline control distance (D Diagram, Fig. 8) corresponds to the outer temporal diameter of the patient's head.

In the diagram obtained (Diagram, Fig. 8) the three dotted vertical lines correspond to

(1) the right external head surface

(2) the geometrical midline

(3) the left external head surface.

In the diagram two horizontal, parallel thin lines are drawn, called echo lines the upper one representing the time axis of the echoencephalogram from the right testpoint (Dx) and the lower one that from the left (Sin).

The initial complex from Dx (EVG, Fig. 8) is indicated by a short vertical line at dotted line 1 (corresponding to the right external head surface) the initial complex from Sin (EVG Fig. 8), is indicated by a short vertical line at dotted line 3 (corresponding to the left external head surface) the arrows from these initial complex indications show the direction of the beam of the transmitted ultrasound.

Echoencephalogram (Dx and Sin)

From the echoencephalogram from the right test point (Dx, EVG Fig. 8) the distances from the initial complex to the midline echo, the distal lateral ventricle echo and the bottom echo are measured. Also the distances from the initial complex to the beginning and the end of completely echo-free zones are measured. The distances measured are then transferred to the diagram the distances from the initial complex to the respective echoes are indicated by short vertical lines at the echoline (Dx), and echo-free zones are indicated by thick horizontal lines, the distances are marked in the diagram from left (vertical line 1) *to* right.

From the echoencephalogram from the left test point (Sin, EVG Fig. 8) the distances corresponding to those from Dx are measured, and transferred to the diagram these distances are marked at the echoline (Sin) from right (vertical line 3) to left.

Lateral ventricle transversal (T)

The distance between the indication (Diagram, Fig. 8) for the distal lateral ventricle echo from Dx (to the *right in* the diagram) and that from Sin (to

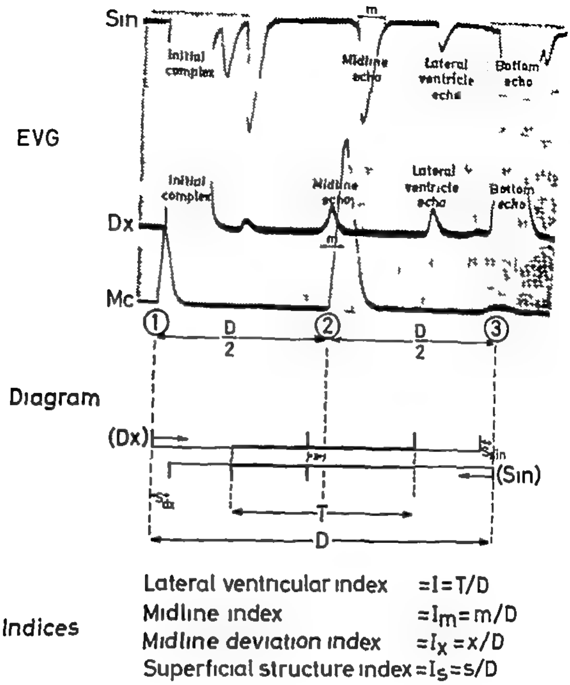


Figure 8 An echoventriculogram (EVG) within the gray field, where Mc represents the midline control, Dx an echoencephalogram from the right and Sin one from the left test point. The graphical representation and index calculations are explained in the text.

Midline control recording (Mc)

From the initial complex and the upward limb of the single deflection in Mc (EVG Fig. 8) vertical parallel dotted lines are drawn downwards, marked 1 and 2 the distance between 1 and 2 is called midline control distance and marked $\frac{D}{2}$ The double midline control distance is also marked with a vertical line (3) parallel with the vertical lines 1 and 2 The double midline control distance (D Diagram, Fig 8) corresponds to the outer temporal diameter of the patient's head.

In the diagram obtained (Diagram, Fig. 8) the three dotted vertical lines correspond to:

(1) the right external head surface
(2) the geometrical midline
(3) the left external head surface.

In the diagram two horizontal parallel thin lines are drawn, called echo lines the upper one representing the time axis of the echoencephalogram from the right testpoint (Dx) and the lower one that from the left (Sin)

The initial complex from Dx (EVG Fig. 8) is indicated by a short vertical line at dotted line 1 (corresponding to the right external head surface) the initial complex from Sin (EVG Fig 8) is indicated by a short vertical line at dotted line 3 (corresponding to the left external head surface) the arrows from these initial complex indications show the direction of the beam of the transmitted ultrasound.

Echoencephalogram (Dx and Sin)

From the echoencephalogram from the right test point (Dx, EVG Fig 8) the distances from the initial complex to the midline echo, the distal lateral ventricle echo and the bottom echo are measured. Also the distances from the initial complex to the beginning and the end of completely echo-free zones are measured. The distances measured are then transferred to the diagram the distances from the initial complex to the respective echoes are indicated by short vertical lines at the echoline (Dx) and echo-free zones are indicated by thick horizontal lines, the distances are marked in the diagram from left (vertical line 1) to right.

From the echoencephalogram from the left test point (Sin, EVG Fig. 8) the distances corresponding to those from Dx are measured, and transferred to the diagram these distances are marked at the echoline (Sin), from right (vertical line 3) to left.

Lateral ventricle transversal (T)

The distance between the indication (Diagram, Fig. 8) for the distal lateral ventricle echo from Dx (to the right in the diagram) and that from Sin (to

the left in the diagram) was measured and has been called the ventricle transversal (T) this is assumed to correspond to the total breadth of the lateral ventricles in the frontal plane.

Lateral ventricle index (I)

The combined breadths of the lateral ventricles (T) is expressed in relation to the temporal diameter (D Fig 8) as a lateral ventricle index $I = T/D$

Midline index (Im)

The width of the midline echo (m) was measured on the echograms (EVG, Fig 8) and expressed in relation to D as a midline index $Im = m/D$

Superficial structure index (Is)

The indications for the bottom echo from echoencephalograms Dx and Sin (EVG Fig 8) are situated near the vertical lines 3 and 1 respectively in the diagram the distances between these indications and the nearest vertical lines (s_{sin} and s_d in the Diagram Fig. 8) were measured and expressed in relation to D as superficial structure indices

$Is_d = \frac{s_{dx}}{D}$ is an expression for the thickness of the superficial structures at the right and $Is_{sin} = \frac{s_{sin}}{D}$ an expression for the corresponding thickness at the left temporal region of the patient s head when s_{dx} is equal to s_{sin} the superficial structure is simply expressed as $Is = \frac{s}{D}$

Midline deviation (x)

In the diagram (Fig 8) the indications for the midline echoes from Dx and Sin are positioned on the same vertical line In cases where this vertical line does not coincide with the geometrical midline, the midline deviation (x) is measured as the distance between the geometrical midline (vertical line 2) and the marks representing the midline echoes if the midline echo marks from echoencephalograms Dx and Sin respectively are not exactly on the same vertical line in the diagram the distance from vertical line 2 to a midline drawn half way between the respective midline echo marks is called x.

Figure 9 Schematic pneumogram compared with enlarged, schematic EVG where Mc = the midline control, Dx the echoencephalogram from the right test point and Sin an inverted echoencephalogram from the left test point.
The positions of the lateral ventricle echoes correspond to the lateral interfaces of the lateral ventricles, and the echo-free zones to the breadths of the lateral ventricles seen in the pneumogram. The position of the cerebral parenchyma in the pneumogram corresponds to small echoes, called parenchymal echoes, in the echoencephalograms (between the lateral ventricle echoes and the bottom echoes)

the left in the diagram) was measured and has been called the ventricle transversal (T) this is assumed to correspond to the total breadth of the lateral ventricles in the frontal plane.

Lateral ventricle index (I)

The combined breadths of the lateral ventricles (T) is expressed in relation to the temporal diameter (D Fig 8) as a lateral ventricle index $I = T/D$

Midline index (Im)

The width of the midline echo (m) was measured on the echograms (EVG Fig 8) and expressed in relation to D as a midline index $Im = m/D$

Superficial structure index (Is)

The indications for the bottom echo from echoencephalograms Dx and Sin (EVG Fig 8) are situated near the vertical lines 3 and 1 respectively in the diagram the distances between these indications and the nearest vertical lines (s_{sin} and s_{dx} in the Diagram Fig 8) were measured and expressed in relation to D as superficial structure indices

$Is_{d} = \frac{s_{dx}}{D}$ is an expression for the thickness of the superficial structures at the right, and $Is_{sin} = \frac{s_{sin}}{D}$ an expression for the corresponding thickness at the left temporal region of the patient's head when s_{dx} is equal to s_{sin} the superficial structure is simply expressed as $Is = \frac{s}{D}$

Midline deviation (x)

In the diagram (Fig. 8) the indications for the midline echoes from Dx and Sin are positioned on the same vertical line. In cases where this vertical line does not coincide with the geometrical midline the midline deviation (x) is measured as the distance between the geometrical midline (vertical line 2) and the marks representing the midline echoes if the midline echo marks from echoencephalograms Dx and Sin respectively are not exactly on the same vertical line in the diagram, the distance from vertical line 2 to a midline drawn half way between the respective midline echo marks is called x.

Fig nr 9 Schematic pneumogram compared with enlarged, schematic EVG, where Mc is the midline control, Dx the echoencephalogram from the right test point and Sin an inverted echoencephalogram from the left test point.
The positions of the lateral ventricle echoes correspond to the lateral interfaces of the lateral ventricles, and the echo-free zones to the breadths of the lateral ventricles seen in the pneumogram. The position of the cerebral parenchyma in the pneumogram corresponds to small echoes, called parenchymal echoes, in the echoencephalograms (between the lateral ventricle echoes and the bottom echoes).

I_m = m/D

Any midline deviation is either expressed in relation to D as a midline deviation index $Ix = \frac{x}{D}$ or is given in millimeters (calculated from Table IV p. 31).

By multiplying the respective indices by 100 expressions are obtained for the combined breadths of the ventricles, the width of the midline echo, the thickness of the superficial structures and the magnitude of the midline deviation in per cent of the cranial diameter in the frontal plane.

Figure 9 shows a schematized pneumogram compared with an enlarged EVG where Mc at the top of the figure denotes a midline control recording, Dx an echoencephalogram from the right test point and Sin an inverted echoencephalogram from the left test point.

Echo-free zones

It can be seen in the figure that the echo-free zones, which are divided medially by the midline echo and delimited laterally by the lateral ventricle echo, correspond to the lateral ventricles in the pneumogram

Parenchymal echoes

Between the lateral ventricle echo and the bottom echo, a series of minimal echoes were noted on both sides, corresponding to the position of the cerebral parenchyma in the pneumogram in the following such echoes will be referred to as parenchymal echoes"

Graphical representation of other recordings

Using the midline control distance of the EVG (Fig 10 A) and one or more midline control distances photographed at other recordings (Fig 10 B) diagrams have been constructed demonstrating three projections of the head in individual cases. A free drawing of the contours of the head is then made with the double midline control distances as diameters (Figs. 10 & 11) the contours being based in all cases on sketches of the shape of the child's head which were made at the time of the examination

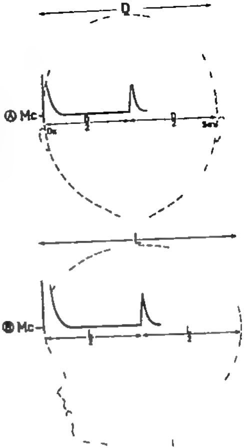
Representation of ultrasound pathway echoes and echo-free zones

Within the constructed dotted lines described above, representing the external contour of the head the echoencephalograms are marked with thin lines (echolines) and the pathway of the ultrasound from the surface of the head is marked with an arrow as in the EVG diagrams. Ideal echoes (see p 45) are marked on the echoline by lines at right angles to it, echo-free zones (which have remained echo-free even at maximal amplification of the apparatus) are marked by heavy lines along the echoline, while the thin echoline represents the extent of the initial complex and echo-producing zones.

Figure 10. Principle for construction of external contour of the head, with the guidance of photographic recordings of midline controls (Mc) according to the transmission method.

A. Mc in temporal region immediately above and anterior to the external auditory opening; the double midline control distance corresponds to the cranial diameter in the frontal plane (D).

B. Mc in fronto-occipital direction; the double midline control distance corresponds to the greatest longitudinal cranial diameter (L).



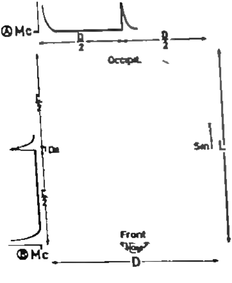


Figure 11. Using D and L according to A and B, respectively, in Fig. 10, together with sketches of the shape of the child head, the external contour of the head, seen from above, has been constructed.

Any midline deviation is either expressed in relation to D as a midline deviation index $Ix = \frac{x}{D}$ or is given in millimeters (calculated from Table IV p. 31).

By multiplying the respective indices by 100 expressions are obtained for the combined breadths of the ventricles, the width of the midline echo, the thickness of the superficial structures and the magnitude of the midline deviation in per cent of the cranial diameter in the frontal plane.

Figure 9 shows a schematized pneumogram compared with an enlarged EVG where Mc at the top of the figure denotes a midline control recording, Dx an echoencephalogram from the right test point and Sin an inverted echoencephalogram from the left test point.

Echo-free zones

It can be seen in the figure that the echo-free zones, which are divided medially by the midline echo and delimited laterally by the lateral ventricle echo, correspond to the lateral ventricles in the pneumogram.

Ideal echoes (see p 45) are marked on the echoline by lines at right angles to it echo-free zones (which have remained echo-free even at maximal amplification of the apparatus) are marked by heavy lines along the echoline, while the thin echoline represents the extent of the initial complex and echo-producing zones.

cephalic patient, where ideal lateral ventricle echoes (see p 45) were obtained.

The index in one and the same patient was determined 17 times in the same number of echoventriculograms, which had been obtained during a period of 30 minutes by 17 independent recordings, where the probe was laid aside between each new recording. The individual index values obtained at these 17 determinations were as follows:

0.67 0.69 0.70 0.70 0.70 0.71 0.67 0.69 0.70 0.70 0.71 0.71 0.67 0.69 0.70 0.70 0.71

The mean value was thus 0.695

Elementary statistical treatment followed, using the equation

$$S = \sqrt{\frac{\sum_{4} \Delta^2}{n-1}} \text{ where}$$

S = the standard deviation of the individual determination,

$\sum_{4} \Delta$ = the sum of the square of the deviations from the mean value and

n = the number of determinations

RESULT Mean value for the 17 determinations = 0.695

S = 0.014

This shows that at this index level the error is about ± 2 %.

IV METHODOLOGICAL ERRORS

For several reasons, echoencephalographic examination of paediatric patients is more difficult than that of adults. For reliable results it is obviously essential that the examiner is absolutely familiar with his apparatus and possesses thorough knowledge of the anatomy of those structures to be investigated. Furthermore, knowledge of the possible sources of error is required, as these may otherwise ruin the results.

Probe against head surface with small curvature radius

The probes which have been available until recently for medical diagnostic use were not actually constructed for this purpose, but for industrial technical work. The surface of the probe is thus completely flat and circular and does not therefore follow the contours of the small, rounded head of an infant.

Since the transmitted effect is directly proportional to the effective radiating surface (cf p. 14), the amplitude of the recorded echoes will be low in cases where the probe surface is only tangential to the surface of the head, which may occur especially in examinations of newborn babies.

On account of the fact that the transmitter is not ideal, i.e. that it does not emit identical waves from each and every point of its surface, gross ampli

Summing up according to the EVG

A Recordings

1 Midline control
2 Echoencephalogram from the right temporal area.
3 Echoencephalogram from the left temporal area.

B Graphical representation

1 A diagram is constructed where the double midline control distance corresponds to the outer diameter of the head (D) in the frontal plane three vertical parallel lines symbolize from left to right the right head surface, the geometrical midline and the left head surface, respectively

2 The distances measured in the right echoencephalogram, from the initial complex to the midline echo, distal lateral ventricle echo and the bottom echo respectively are transferred to the diagram and marked in from left to right.

3 The distances measured, in the left echoencephalogram, from the initial complex to the midline echo distal lateral ventricle echo and the bottom echo respectively are transferred to the diagram and marked in from right to left.

C Index calculations

1 The ventricle transversal (T) (between the two marks for the lateral walls of the distal lateral ventricles in the diagram) is measured and expressed in relation to D as a lateral ventricle index $I = T/D$

2 The breadth of the midline echo (m) is measured and expressed in relation to D as a midline index $Im = m/D$

3 The distance (s) between the marks for the bottom echoes on each side and the adjacent vertical line in the diagram is measured and expressed in relation to D as a superficial index $Is = s/D$

4 The distance (x) between the marks for the midline echoes and the geometrical midline in the diagram is measured and expressed in relation to D as a midline deviation index $Ix = x/D$

Accuracy and standard deviation in lateral ventricle index determinations

In order to determine the accuracy of the lateral ventricle index determination the standard deviation for index determination was studied in a hydro-

cephalic patient, where ideal lateral ventricle echoes (see p. 45) were obtained.

The *index in one and the same patient* was determined 17 times in the same number of echoventriculograms, which had been obtained during a period of 30 minutes by 17 independent recordings, where the probe was laid aside between each new recording. The individual index values obtained at these 17 determinations were as follows:

0.67 0.69 0.70 0.70 0.70 0.71 0.67 0.69 0.70 0.70 0.71 0.71 0.67 0.69 0.70 0.70 0.71

The mean value was thus 0.695.

Elementary statistical treatment followed, using the equation

$$S = \sqrt{\frac{\sum_1 \Delta_i}{n-1}} \text{ where}$$

S = the standard deviation of the individual determination,

$\sum_1 \Delta$ = the sum of the square of the deviations from the mean value and

n = the number of determinations.

RESULT: Mean value for the 17 determinations = 0.695

$S = 0.014$

This shows that at this index level the error is about ± 2 %.

IV. METHODOLOGICAL ERRORS

For several reasons, echoencephalographic examination of paediatric patients is more difficult than that of adults. For reliable results it is obviously essential that the examiner is absolutely familiar with his apparatus and possesses thorough knowledge of the anatomy of those structures to be investigated. Furthermore, knowledge of the possible sources of error is required, as these may otherwise ruin the results.

Probe against head surface with small curvature radius

The probes which have been available until recently for medical diagnostic use were not actually constructed for this purpose, but for industrial technical work. The surface of the probe is thus completely flat and circular and does not therefore follow the contours of the small, rounded head of an infant.

Since the transmitted effect is directly proportional to the effective radiating surface (cf. p. 14), the amplitude of the recorded echoes will be low in cases where the probe surface is only tangential to the surface of the head, which may occur especially in examinations of newborn babies.

On account of the fact that the transmitter is not ideal, i.e. that it does not emit identical waves from each and every point of its surface, gross ampli-

tude distortion in the near field may occur this contributes towards the difficulties in obtaining echoencephalograms with ideal echoes in examinations of newborn babies, with small cranial diameters, where this "dangerous near" field region coincides with the distance to be studied. These difficulties are reduced if a probe with a small transmitter diameter is used and also if the echoencephalographic picture representing the distal, and not the proximal half of the head is evaluated in accordance with the EVG evaluation.

Contact between surface of probe and object of examination

For satisfactory results it is necessary for good contact to be obtained between the probe surface and the surface of the examination object, and the contact

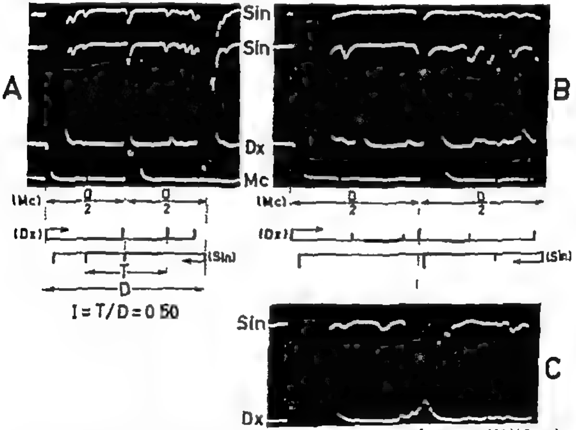

Figure 12 A. EVG of an infant with moderate hydrocephalus. (Range of apparatus 100 × 2 mm) Notation, diagrammatic representation and calculation of indices as in Figure 8. Between the midline echoes and the lateral ventricle echoes are noted broadened echo-free zones in all echoencephalograms.
B and C. Recordings on the same patient, photographed 10—20 seconds later than A. (Range of apparatus 250 × 0.5 mm) In B a series of irregular non-reproducible echoes (artefact echoes) are noted instead of the distal echo-free zones and lateral ventricle echoes. In C the ordinary echoencephalogram is totally replaced by artefact echoes.

medium between these two surfaces must be thin enough to be regarded as negligible when measuring the distances. If the probe is pressed *hard against* the surface of the examination object, and the pressure then released somewhat, the contact medium can be pressed away and air can pass in between the two surfaces, which will give rise to total reflection of ultrasound (see p. 15).

In attempts at seeking "ideal" lateral ventricle echoes (see below) in infants, the probe must be rocked and moved slightly over the test point; in doing this small air bubbles may easily pass in to the layer of liquid paraffin and cause so-called artefact echoes, which may be projected on to the oscilloscopic tracing and give rise to erroneous interpretation of the echoencephalogram.

Figure 12 A shows a *lege artis* EVG examination on a patient with moderate hydrocephalus. Figure 12 B shows an EVG examination on the same infant, after the probe had been rocked very slightly on the surface of the head, and was then again held still against the same point as before; the layer of contact medium between the two surfaces remained unchanged in thickness, but through the transparent protective ring a few air bubbles, the size of a pin-head, were seen under the contact surface of the probe. A series of confluent, non-reproducible echoes are now superimposed on the ordinary echoencephalogram tracing, and are seen over the site of the distal echo-free zone (cf. recording A). Such artefact echoes may be mistaken for parenchymal echoes, and echo-free zones due to dilated ventricles may be overlooked. Figure 12 C shows another recording in which the ordinary echoencephalogram tracing is almost obliterated by artefacts.

Positioning of the probe in relation to the position of the reflecting surface

For accurate distance measurement with the ultrasonic echo method, the surface of the probe should run parallel with the reflecting surface. When this criterion is fulfilled, so-called *ideal echoes* are obtained, where the upward limb of the deflection is thin and rises practically at right angles to the time axis of the oscilloscopic tracing (Fig. 13:I).

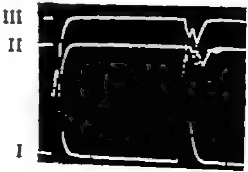

Figure 13 I Ideal echo: reflecting surface parallel to the surface of the probe.
II and III Wide echoes: reflecting surface positioned at an angle of about 8° to the surface of the probe.
Five camera exposures are made for each recording.

If the probe is held at an angle to the reflecting surface, broad, multi peaked echoes may be obtained. Figure 13 II and III show such echoes in experiments in which this angle was about 8

Even with a relatively moderate angle between the surface of the probe and the reflecting surface, total reflection (cf p 15) can occur on return of the ultrasound through the bone.

Position of the head

At the EVG examination the position of the infant's head is of importance for the results fairly considerable intracranial displacements may occur if for example, a hydrocephalic patient is turned from the supine to the lateral position Therefore in order to obtain comparative results the same position should be used for all examinations, the most suitable being the supine position.

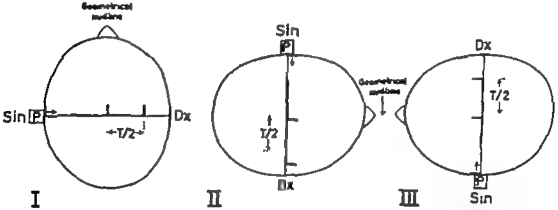

Figure 14 Schematic presentation of echoencephalograms with regard to midline echo and distal lateral ventricle echo in an infant with moderate hydrocephalus, recorded from the left test point (P = the probe) The figure shows displacement of the midline echo and the lateral ventricle echo in the right lateral position (II) as well as minimal displacement of the midline echo in the left lateral position (III) compared to the supine position (I)

Figure 14 shows schematically the results obtained with respect to the right lateral ventricle, on examination of an infant with moderate hydrocephalus. On examination in the supine position (I) the lateral ventricle index was calculated to be 0.60. With the right lateral position (II), fairly considerable deviation of the right lateral ventricle echo was noted, and a lateral ventricle index of 0.85 was obtained; in addition, slight deviation of the midline echo to the right was observed. When the infant was examined in the left lateral position (III) (with its head resting against the probe (P)) no deviation of the right lateral ventricle echo was noted, but slight deviation of the midline echo to the left was seen.

Geometry concerning the ultrasound pathway

The human ventricular system is complicated both in form and distribution (Fig. 15), and its marginal surfaces run parallel with the cranial surface only sporadically.

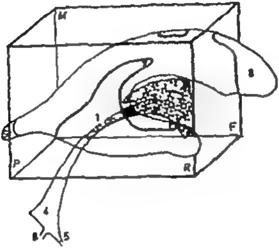

Figure 15 Schematic illustration of the normal human ventricular system, showing its complicated geometrical configuration. The greater part (grey) of the ventricular system is enclosed in an imaginary plexiglass box (light grey field = right lateral ventricle, dark grey field = 1 aqueduct of Sylvius, 2 foramen of Monro, 3 third ventricle).
The dorsal wall (M) of the plexiglass box represents the medial plane of the head. The aqueduct (1) thus cuts through its posterior inferior corner and the fourth ventricle (4) with the foramen of Luschka (5) to the right and the foramen of Magendie (6) in the midplane, lies outside the plexiglass box.
The proximal wall (R) is tangential to the right wall of the lateral ventricle's cella media (7), against which ultrasound is usually reflected on EVG. The frontal horn of the lateral ventricle (8) protrudes through the front wall (F) more medially than does the occipital horn (9) through the posterior wall (P). The temporal horn (10) projects through the box both frontally and laterally (i.e. through walls P and R).

In echoencephalographic examination from the test point, the ultrasonic beam can be made to fall at right angles to the marginal surfaces of the lateral ventricles at the level of the cellae mediae, whereby the beam meets both convex and concave, more or less spherical surfaces with varying radii. Thus for adequate evaluation of an echoencephalogram, with special regard to the ventricular system, consideration must be taken of the geometrical conditions and physical laws of radiation.

An attempt to explain the influence of the curvature radius of a reflecting spherical surface is made in Figure 16.

If the probe is held at an angle to the reflecting surface, broad, multi peaked echoes may be obtained. Figure 13:II and III show such echoes in experiments in which this angle was about 8°

Even with a relatively moderate angle between the surface of the probe and the reflecting surface, total reflection (cf p 15) can occur on return of the ultrasound through the bone.

Position of the head

At the EVG examination the position of the infant's head is of importance for the results fairly considerable intracranial displacements may occur if for example a hydrocephalic patient is turned from the supine to the lateral position Therefore, in order to obtain comparative results the same position should be used for all examinations, the most suitable being the supine position.

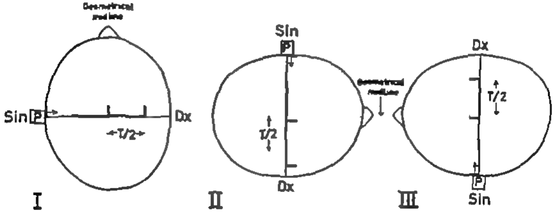

Figure 14 Schematic presentation of echoencephalograms with regard to midline echo and distal lateral ventricle echo in an infant with moderate hydrocephalus, recorded from the left test point (P = the probe) The figure shows displacement of the midline echo and the lateral ventricle echo in the right lateral position (II) as well as minimal displacement of the midline echo in the left lateral position (III) compared to the supine position (I)

Even with a relatively moderate angle between the surface of the probe and the reflecting surface, total reflection (cf p. 15) can occur on return of the ultrasound through the bone.

Position of the head

At the EVG examination the position of the infant's head is of importance for the results fairly considerable intracranial displacements may occur if for example, a hydrocephalic patient is turned from the supine to the lateral position. Therefore, in order to obtain comparative results the same position should be used for all examinations, the most suitable being the supine position

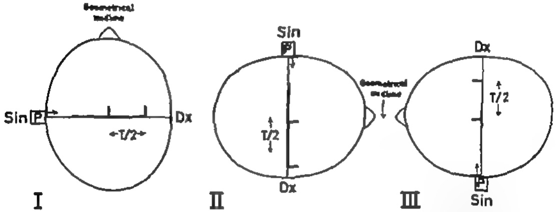

Figure 14 Schematic presentation of echoencephalograms with regard to midline echo and distal lateral ventricle echo in an infant with moderate *hydrocephalus, recorded from the left test point* (P = the probe) The figure shows displacement of the midline echo and the lateral ventricle echo in the right lateral position (II) as well as minimal displacement of the midline echo in the left lateral position (III) compared to the supine position (I).

Figure 14 shows schematically the results obtained with respect to the right lateral ventricle, on examination of an infant with moderate hydrocephalus. On examination in the supine position (I) the lateral ventricle index was calculated to be 0.60. With the right lateral position (II), fairly considerable deviation of the right lateral ventricle echo was noted, and a lateral ventricle index of 0.85 was obtained; in addition slight deviation of the midline echo to the right was observed When the infant was examined in the left lateral position (III) (with its head resting against the probe (P)) no deviation of the right lateral ventricle echo was noted, but slight deviation of the midline echo to the left was seen.

Ray 4 falls at right angles to D and the reflected ultrasound returns to the same point on P from which it is transmitted.

Since the distance P—D is greater than P—C, it takes longer time for ray 4 to return to P after reflection against D than for ray 1 after reflection against C therefore in the echogram the distance from the initial complex to $Echo_D$ must be longer than to $Echo_C$. If the distance between $Echo_C$ and $Echo_D$ is small, these echoes will con erge in the oscilloscope and will appear as double-peaked broad based echo.

It is thus evident from the above that

1) the amplitude of the echo increases with the curvature radius of a reflecting surface (e.g. a dilated lateral ventricle) and
2) a reflecting surface of irregular configuration may give echoes that are multi peaked and increased in width (e.g. small ventricles with irregularly formed surfaces).

In figure 17 an attempt is made to show how reflection against concave and convex spherical surfaces may influence the echoencephalographic recording.

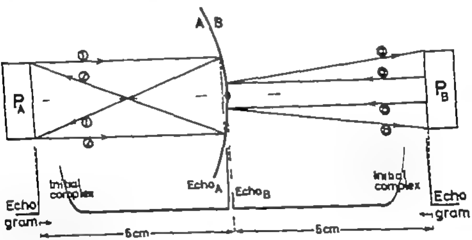

Figure 17 Amplitude of the echo in relation to conca and con ex reflecting surfaces. See tex for further details

A (Fig. 17) shows concave, spherical surface (≡ the lateral wall of the distal lateral entricle at an EVG-examination) with radius of 5 cm, reflecting parallel ultrasound; it is imagined tha the ultrasound is transmitted from probe (P_A), 2 cm in diameter placed with the centre of its radiating surface in the centre of the sphere, 5 cm from 0. All ultrasound that is transmitted from P_A and reflected against A returns to P even the marginal rays 1 and 2, because of the focusing properties of the concave surface thus an echo of high amplitude will ppear from surface A.

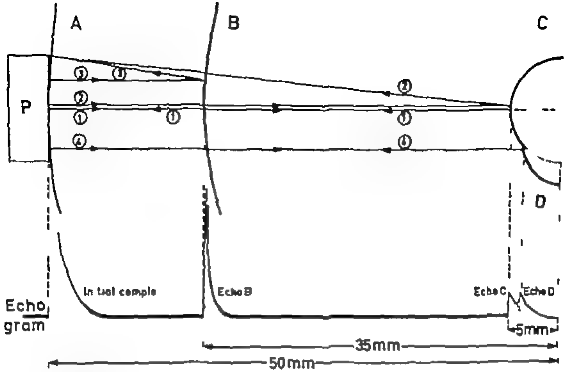

Figure 16. Amplitude of the echo as a function of the curvature radius of the reflecting surface, and demonstration of multi-peaked, wide echoes. See text for further details.

In Figure 16, it is imagined that a parallel ultrasound beam is transmitted from the probe (P), which is held closely against a spherical surface (A) with a radius of 50 mm (cf an infant's head). In its path, the beam encounters a spherical surface (B) with a radius of 35 mm (cf a dilated lateral ventricle) and also a spherical surface (C) with a radius of 5 mm the lower part of the circumference of sphere C is contiguous to a curved surface (D) with a smaller curvature radius than C (cf a small lateral ventricle or a dilated third ventricle) The central ray (1) falls at right angles to both B and C, and reflected ultrasound returns to the same point on P from which it was transmitted. Ray 2 falls against C at such an angle that the reflected ultrasound returns to the outer margin of P; thus only ultrasound that is transmitted from P from within a radius of the same order of size as the distance between rays 1 and 2 can be detected by P after reflection against C. Ray 3 falls against B at such an angle that the *reflected ultrasound* reaches the outer margin of P thus ultrasound that is transmitted from P from within a radius of the same order of size as the distance between rays 1 and 3 can be detected by P after reflection against B Since the returning intensities are proportional to the effective transmitting surface, and the amplitudes are proportional to the square root of the intensities (p. 14), it follows that the amplitudes of the echoes are proportional to the radii of the effective transmitting surfaces.

The radius between rays 1 and 3 is considerably greater than that between rays 1 and it follows that the amplitude of an echo resulting from reflection against spherical surface with a large curvature radius ($Echo_B$) must be greater than that of an echo occurring from reflection against a spherical surface with a small curvature radius ($Echo_C$).

Ray 4 falls at right angles to D and the reflected ultrasound returns to the same point on P *from which it is transmitted.*

Since the distance P—D is greater than P—C, it takes a longer time for ray 4 to return to P after reflection against D than for ray 1 after reflection against C; *therefore in the echogram* the distance from the initial complex to $Echo_D$ must be longer than to $Echo_C$. If the distance between $Echo_C$ and $Echo_D$ is small, these echoes will converge in the oscilloscope and will appear as a double-peaked broad based echo.

It is thus evident from the above that

1) the *amplitude of the echo increases with the curvature radius of a reflecting* surface (e.g. a dilated lateral ventricle) and
2) a reflecting surface of irregular configuration may give echoes that are multi-peaked and increased in width (e.g. small ventricles with *irregularly* formed surfaces).

In figure 17 an attempt is made to show how reflection against concave and convex spherical surfaces may influence the echoencephalographic recording.

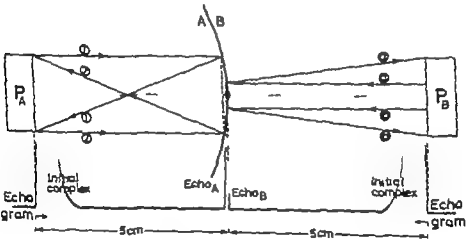

Figure 17. Amplitude of the echo in relation to concave and convex reflecting surfaces. See text for further details.

A (Fig. 17) shows a concave, spherical surface (e.g. the lateral wall of the distal lateral ventricle at an EVG-examination) with a radius of 5 cm, reflecting parallel ultrasound. It is imagined that the ultrasound is transmitted from a probe (P_A), 2 cm in *diameter placed* with the centre of its radiating surface in the centre of the sphere, 5 cm from 0. All ultrasound that is transmitted from P_A and reflected against A *returns to P* even the marginal rays 1 and 2, because of the focusing properties of the concave surface; thus an echo of high amplitude will appear from surface A.

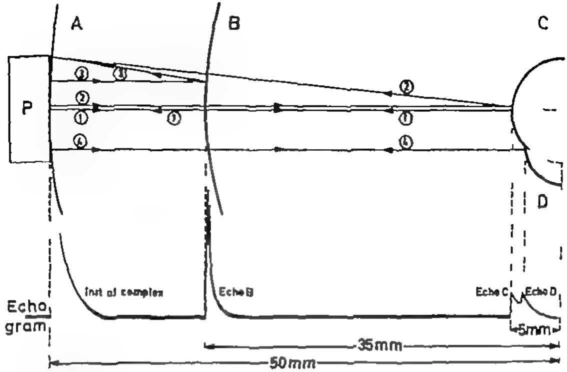

Figure 16 Amplitude of the echo as a function of the curvature radius of the reflecting surface and demonstration of multi-peaked, wide echoes. See text for further details.

In Figure 16, it is imagined that a parallel ultrasound beam is transmitted from the probe (P) which is held closely against a spherical surface (A) with a radius of 50 mm (cf an infant's head); in its path, the beam encounters a spherical surface (B) with a radius of 35 mm (cf a dilated lateral ventricle) and also a spherical surface (C) with a radius of 5 mm; the lower part of the circumference of sphere C is contiguous to a curved surface (D) with a smaller curvature radius than C (cf a small lateral ventricle or a dilated third ventricle). The *central ray (1) falls at right angles to both B and C, and reflected ultrasound returns* to the same point on P from which it was transmitted. Ray 2 falls against C at such an angle that the reflected ultrasound returns to the outer margin of P thus only ultrasound that *is transmitted from P from within a radius of the same order of size as the distance between* rays 1 and 2 can be detected by P after reflection against C. Ray 3 falls against B at such an angle that the reflected ultrasound reaches the outer margin of P; thus ultrasound that *is transmitted from P from within a radius of the same order of size as the distance between* rays 1 and 3 can be detected by P after reflection against B. Since the returning intensities are proportional to the effective transmitting surface, and the amplitudes are proportional *to the square root of the intensities (p. 14), it follows that the amplitudes of the echoes* are proportional to the radii of the effective transmitting surfaces.

The radius between rays 1 and 3 is considerably greater than that between rays 1 and 2 it follows that the *amplitude of an echo resulting from reflection against a spherical surface* with a large curvature radius (Echo$_B$) must be greater than that of an echo occurring from reflection against a spherical surface with a small curvature radius (Echo$_C$)

ointment is easy to remove, and is possibly preferable for adults and older children with thicker and coarser hair

Owing to the fineness and sparsity of an infant's hair it is not necessary to shave the part of the head where the probe is to be placed, in order to obtain good contact and to avoid totally reflecting air masses between the surface of the probe and that of the head. It is more difficult however to obtain good contact between the probe and the surface of the head in infants than in adults, especially as infants seldom lie absolutely still further due to the plane surface of the probe (cf p. 43), difficulties may be encountered in finding a sufficiently large plane surface on an infant's small, often bulging head, to obtain a large enough effective transceving area.

On echoventriculographic examination, the amplification of the apparatus must be varied so that both the midline and bottom echoes, and the ventricular and parenchymal echoes can be detected, in order that any echo-free zones can be ascribed their correct diagnostic value. An echoencephalogram representing the intracranial anatomy is reproducible artefact echoes vary however from one examination to another in the same patient. If an echoencephalogram with uncharacteristic, flat, irregularly shaped echoes is obtained, the examination should be repeated after removing the contact medium from the two surfaces and making a fresh application.

The probe must be rocked and moved slightly against the head until an ideal (or almost ideal) echo is recorded, which means that the ultrasound falls at right angles to the reflecting surface being examined otherwise, accurate calculation of distances will not be possible. Therefore, the localization of the probe on the patient's head cannot be defined mathematically as so many millimetres from, for example, the external auditory opening, owing to individual variations in the configuration of both the entire head and the lateral ventricles, it is necessary to seek a region from which as ideal echoes as possible can be found.

Midline control

For psychological reasons I have found it best in infants and children to start the examination with the midline control. This is quickly performed and gives the patient no time to become irritated. When experience has then taught him that the examination is not harmful it is usually possible to continue undisturbed with the stages that require greater concentration, namely the search for the midline and ventricle echoes. In the few cases in which the subsequent echo recording cannot be made from the same point as for the midline control, for example owing to the shape of the skull, a new midline

B (Fig. 17) is the convex surface of the same sphere, *reflecting parallel ultrasound* (e.g. the proximal wall of a lateral ventricle at an echoencephalographic examination) it is imagined that this ultrasound is transmitted from a probe (P_B) also with a diameter of 2 cm, placed outside the convex surface with its centre 5 cm from 0. Parallel ultrasound transmitted from P_B is reflected in B as divergent rays only rays that are transmitted from the centre of P_B within a diameter equal to the distance between rays a and b, return to P_B after reflection.

The diameter between rays 1 and 2 (from the concave reflecting surface A) is considerably greater than that between rays a and b (from the convex surface B) it follows (cf pp. 14 and 48) that the echoes from the concave surface will be of greater amplitude than the corresponding echoes from the convex surface.

The distance between the surface of the probe and the reflecting region is somewhat shorter for the marginal rays 1 and 2 than the corresponding distance for the marginal rays a and b from this it follows that the distance between the initial complex of the echogram and the echo from the concave surface ($Echo_A$) is not completely identical with the corresponding distance to the convex surface ($Echo_B$).

It is evident from the above that echoes from parallel ultrasound, transmitted from the same probe at the same distance from a curved reflecting surface

1) will be of higher amplitude when the reflecting surface is positioned so that it is concave, than when it is convex
2) will appear at a somewhat smaller distance from the probe when the reflecting surface is concave, than when it is convex.

V COMMENTS CONCERNING THE METHOD

Position of the head

In an EVG examination special attention must be paid to the position of the infant's head to avoid errors in the assessment due to intracranial displacements (cf p 46 and Fig. 14) It is therefore of advantage if the EVG examination is always performed in the supine position.

Application of probe

As a contact medium between the surface of the head and the probe liquid paraffin is preferable to more viscous media such as, for example, the water soluble ointment which is supplied with the apparatus. Liquid paraffin usually gives good contact and allows sliding of the probe on the surface of head for the EVG examination. With the contact ointment, each time the probe needs to be moved a new application of ointment is required on the other hand this

ointment is easy to remove, and is possibly preferable for adults and older children with thicker and coarser hair

Owing to the fineness and sparsity of an infant's hair it is not necessary to shave the part of the head where the probe is to be placed, in order to obtain good contact and to avoid totally reflecting air masses between the surface of the probe and that of the head. It is more difficult however to obtain good contact between the probe and the surface of the head in infants than in adults, especially as infants seldom lie absolutely still further due to the plane surface of the probe (cf p. 43) difficulties may be encountered in finding a sufficiently large plane surface on an infant's small, often bulging head, to obtain a large enough effective transceiving area.

On echoventriculographic examination, the amplification of the apparatus must be varied so that both the midline and bottom echoes, and the ventricular and parenchymal echoes can be detected, in order that any echo-free zones can be ascribed their correct diagnostic value. An echoencephalogram representing the intracranial anatomy is reproducible artefact echoes vary however from one examination to another in the same patient. If an echoencephalogram with uncharacteristic, flat, irregularly shaped echoes is obtained, the examination should be repeated after removing the contact medium from the two surfaces and making a fresh application.

The probe must be rocked and moved slightly against the head until an ideal (or almost ideal) echo is recorded, which means that the ultrasound falls at right angles to the reflecting surface being examined otherwise, accurate calculation of distances will not be possible. Therefore, the localization of the probe on the patient's head cannot be defined mathematically as so many millimetres from, for example, the external auditory opening owing to individual variations in the configuration of both the entire head and the lateral ventricles t is necessary to seek a region from which as ideal echoes as possible can be found.

Midline control

Fo psychological reasons I have found it best in infants and children to start the examination with the midline control. This is quickly performed and gives the patient no time to become irritated. When experience has then taught him that the examination is not harmful it is usually possible to continue undisturbed w th the stages that require greater concentration namely the search for the midline and ventricle echoes. In the few cases in which the subsequent echo recording cannot be made from the same point as for the midline control for example owing to the shape of the skull, a new midline

control is made from the same area on the head at which the probe must be placed for the echo recording

Echo examination

In order to obtain ideal echoes, the distal lateral ventricle echo is more suitable than the proximal one partly for geometrical reasons because of the focusing properties of a concave reflecting surface (cf p 50) and partly because the proximal echo may lie so far laterally that it disappears in the initial complex or appears within the near field, where gross amplitude distortion may occur (cf p 43)

Echoes from a curved surface with a large radius have a higher amplitude than when the radius is small (cf p 48) Thus it is possible to obtain ideal echoes from the lateral wall of the distal lateral ventricle when the ventricular system is dilated which makes it possible to determine fairly exactly the size of dilated ventricles.

It is more difficult and sometimes impossible, to obtain ideal echoes from a normal lateral ventricle its curved and often irregularly shaped surface with a small curvature radius will give multiple mutually confluent echoes of low amplitude (see p 49) measurements of the ventricular size in normal infants and children will therefore be more approximative than in patients with a dilated ventricular system However a normal echoencephalogram in paediatric patients is characterized by parenchymal echoes covering almost the whole recording therefore it is not necessary for diagnostic purposes, to obtain an exact value of the lateral ventricle index in order to make sure that the lateral ventricles are not dilated

In patients with thicker skull bone the higher degree of absorption (cf p 17) may cause the distal ventricle echo to disappear but it may still be possible to obtain echoes from the proximal lateral ventricle. For compatible results, it is necessary to use comparable surfaces since the echoes from a concave and a convex surface of the same curvature differ somewhat (cf p 49)

On its pathway through the brain ultrasound passes through different tissues at somewhat varying speeds. However the differences in sound velocity in the brain (1515 m/sec) and cerebrospinal fluid (1504 m/sec) (cf p 14) are so small as to be negligible in an echoencephalogram a difference of less than 2/3 mm would be obtained if the skull cavity were full of cerebrospinal fluid instead of cerebral parenchyma.

A reflecting structure composed of several differently positioned components with acoustic properties differing from those of the environment may give rise to a broad based, multi peaked echo complex that is in such cases where

the different reflecting components lie so close together as to give confluence of the individual echoes on the echoencephalogram this will be seen in patients with cerebral tumour structures or in cases of dilated third ventricle where the dilatation does not reach such a degree *as to give individual echoes* from each of its lateral walls, separated by an echo-free zone.

Summing up: Broad-based, multiple-peaked echoes of low amplitude may be an expression of

1 the character of the reflecting structures, e.g. a dilated third ventricle or a tumour
2. the geometry of the structures and ultrasonic beam, e.g. in cases where the probe is not lying parallel with the reflecting *surface or the contour of the* reflecting surface is irregularly shaped
3 poor contact between the probe and the surface of the head.

By careful investigation and an aim at reproducibility of the results, it can usually be determined from the oscilloscopic tracing which of these factors is the underlying cause.

Photographic recording

The photographic recording constitutes only one, and at times a less important part of the whole examination.

When performing EVG it is not always possible to obtain a photographic recording that fully justifies the tracing observed in the oscilloscope. An ideal echo seen in the oscilloscope may be of lower amplitude, and sometimes broader on the photographic recording, for example if the patient moves his head just at the moment when the photograph is taken, so that the probe lies at a slight angle *to the echo-producing surface. It is essential, therefore,* that the photographic recording is assessed at the time of the examination, so that, if necessary the recording may be repeated so as to agree with the oscillogram.

Graphical rep esentation

*If the EVG examination has been carried out with care and with the avo*idance of the sources of error discussed above, evaluation of the photographic recording *according to the described* method of graphical representation and index calculation can, after a short period of training, be performed simply and quickly This will give a clear picture of the ventricular system in relation to the external diameter of the head when presenting a report on the result of the EVG examination I usually enclose a copy of the diagram, with the external contours of the head and ventricles *dotted in* approximately over

control is made from the same area on the head at which the probe must be placed for the echo recording

Echo examination

In order to obtain ideal echoes the distal lateral ventricle echo is more suitable than the proximal one, partly for geometrical reasons because of the focusing properties of a concave reflecting surface (cf p 50) and partly because the proximal echo may lie so far laterally that it disappears in the initial complex or appears within the near field where gross amplitude distortion may occur (cf p 43)

Echoes from a curved surface with a large radius have a higher amplitude than when the radius is small (cf p 48) Thus it is possible to obtain ideal echoes from the lateral wall of the distal lateral ventricle when the ventricular system is dilated which makes it possible to determine fairly exactly the size of dilated ventricles.

It is more difficult, and sometimes impossible to obtain ideal echoes from a normal lateral ventricle its curved and often irregularly shaped surface with a small curvature radius will give multiple, mutually confluent echoes of low amplitude (see p 49) measurements of the ventricular size in normal infants and children will therefore be more approximative than in patients with a dilated ventricular system. However a normal echoencephalogram in paediatric patients is characterized by parenchymal echoes covering almost the whole recording therefore it is not necessary for diagnostic purposes, to obtain an exact value of the lateral ventricle index in order to make sure that the lateral ventricles are not dilated

In patients with thicker skull bone, the higher degree of absorption (cf p 17) may cause the distal ventricle echo to disappear but it may still be possible to obtain echoes from the proximal lateral ventricle For compatible results, it is necessary to use comparable surfaces since the echoes from a concave and a convex surface of the same curvature differ somewhat (cf p 49)

On its pathway through the brain ultrasound passes through different tissues at somewhat varying speeds However the differences in sound velocity in the brain (1515 m/sec) and cerebrospinal fluid (1504 m/sec) (cf p 14) are so small as to be negligible in an echoencephalogram, a difference of less than 2/3 mm would be obtained if the skull cavity were full of cerebrospinal fluid instead of cerebral parenchyma

A reflecting structure composed of several differently positioned components with acoustic properties differing from those of the environment may give rise to a broad based multi peaked echo complex that is in such cases where

the different reflecting components lie so close together as to give confluence of the individual echoes on the echoencephalogram this will be seen in patients with cerebral tumour structures or in cases of dilated third ventricle where the dilatation does not reach such a degree as to give individual echoes from each of its lateral walls, separated by an echo-free zone.

Summing up: Broad-based, multiple-peaked echoes of low amplitude may be an expression of:

1 the character of the reflecting structures, e.g. a dilated third ventricle or a tumour.
2. the geometry of the structures and ultrasonic beam, e.g. in cases where the probe is not lying parallel with the reflecting surface or the contour of the reflecting surface is irregularly shaped
3 poor contact between the probe and the surface of the head.

By careful investigation and an aim at reproducibility of the results, it can usually be determined from the oscilloscopic tracing which of these factors is the underlying cause.

Photographic recording

The photographic recording constitutes only one, and at times a less important part of the whole examination.

When performing EVG it is not always possible to obtain a photographic recording that fully justifies the tracing observed in the oscilloscope. An ideal echo seen in the oscilloscope may be of lower amplitude, and sometimes broader on the photographic recording, for example if the patient moves his head just at the moment when the photograph is taken so that the probe lies at a slight angle to the echo-producing surface. It is essential, therefore, that the photographic recording is assessed at the time of the examination, so that, if necessary the recording may be repeated so as to agree with the oscillogram.

Graphical representation

If the EVG examination has been carried out with care and with the avoidance of the sources of error discussed above evaluation of the photographic recording according to the described method of graphical representation and index calculation can, after a short period of training, be performed simply and quickly This will give a clear picture of the ventricular system in relation to the external diameter of the head when presenting a report on the result of the EVG examination I usually enclose a copy of the diagram, with the external contours of the head and ventricles dotted in approximately over

control is made from the same area on the head at which the probe must be placed for the echo recording

Echo examination

In order to obtain ideal echoes, the distal lateral ventricle echo is more suitable than the proximal one, partly for geometrical reasons because of the focusing properties of a concave reflecting surface (cf p 50) and partly because the proximal echo may lie so far laterally that it disappears in the initial complex or appears within the near field where gross amplitude distortion may occur (cf p 43)

Echoes from a curved surface with a large radius have a higher amplitude than when the radius is small (cf p 48) Thus it is possible to obtain ideal echoes from the lateral wall of the distal lateral ventricle when the ventricular system is dilated which makes it possible to determine fairly exactly the size of dilated ventricles

It is more difficult, and sometimes impossible to obtain ideal echoes from a normal lateral ventricle its curved and often irregularly shaped surface with a small curvature radius will give multiple mutually confluent echoes of low amplitude (see p 49) measurements of the ventricular size in normal infants and children will therefore be more approximative than in patients with a dilated ventricular system However a normal echoencephalogram in paediatric patients is characterized by parenchymal echoes covering almost the whole recording therefore it is not necessary for diagnostic purposes to obtain an exact value of the lateral ventricle index in order to make sure that the lateral ventricles are not dilated.

In patients with thicker skull bone, the higher degree of absorption (cf p 17) may cause the distal ventricle echo to disappear but it may still be possible to obtain echoes from the proximal lateral ventricle For compatible results, it is necessary to use comparable surfaces since the echoes from a concave and a convex surface of the same curvature differ somewhat (cf p 49)

On its pathway through the brain ultrasound passes through different tissues at somewhat varying speeds. However the differences in sound velocity in the brain (1515 m/sec) and cerebrospinal fluid (1504 m/sec) (cf p 14) are so small as to be negligible in an echoencephalogram a difference of less than 2/3 mm would be obtained if the skull cavity were full of cerebrospinal fluid instead of cerebral parenchyma

A reflecting structure composed of several differently positioned components with acoustic properties differing from those of the environment, may give rise to a broad based multi peaked echo complex that is in such cases where

the different reflecting components lie so close together as to give confluence of the individual echoes on the echoencephalogram this will be seen in patients with cerebral tumour structures or in cases of dilated third ventricle where the dilatation does not reach such a degree as to give individual echoes from each of its lateral walls, separated by an echo-free zone.

Summing up: Broad-based, multiple-peaked echoes of low amplitude may be an expression of

1. the character of the reflecting structures, e.g. a dilated third ventricle or a tumour;
2. the geometry of the structures and ultrasonic beam, e.g. in cases where the probe is not lying parallel with the reflecting surface or the contour of the reflecting surface is irregularly shaped
3. poor contact between the probe and the surface of the head.

By careful investigation and an aim at reproducibility of the results, it can usually be determined from the oscilloscopic tracing which of these factors is the underlying cause.

Photographic recording

The photographic recording constitutes only one, and at times a less important part of the whole examination.

When performing EVG it is not always possible to obtain a photographic recording that fully justifies the tracing observed in the oscilloscope. An ideal echo seen in the oscilloscope may be of lower amplitude, and sometimes broader on the photographic recording, for example if the patient moves his head just at the moment when the photograph is taken, so that the probe lies at a slight angle to the echo-producing surface. It is essential, therfore, that the photographic recording is assessed at the time of the examination, so that, if necessary the recording may be repeated so as to agree with the oscillogram.

Graphical representation

If the EVG examination has been carried out with care and with the avoidance of the sources of error discussed above, evaluation of the photographic recording according to the described method of graphical representation and index calculation can, after a short period of training, be performed simply and quickly This will give a clear picture of the ventricular system in relation to the external diameter of the head when presenting a report on the result of the EVG examination I usually enclose a copy of the diagram, with the external contours of the head and ventricles dotted in approximately over

control is made from the same area on the head at which the probe must be placed for the echo recording

Echo examination

In order to obtain ideal echoes, the distal lateral ventricle echo is more suitable than the proximal one, partly for geometrical reasons because of the focusing properties of a concave reflecting surface (cf p 50) and partly because the proximal echo may lie so far laterally that it disappears in the initial complex or appears within the near field where gross amplitude distortion may occur (cf p 43)

Echoes from a curved surface with a large radius have a higher amplitude than when the radius is small (cf p 48) Thus it is possible to obtain ideal echoes from the lateral wall of the distal lateral ventricle when the ventricular system is dilated which makes it possible to determine fairly exactly the size of dilated ventricles.

It is more difficult and sometimes impossible to obtain ideal echoes from a normal lateral ventricle its curved and often irregularly shaped surface with a small curvature radius will give multiple mutually confluent echoes of low amplitude (see p 49) measurements of the ventricular size in normal infants and children will therefore be more approximative than in patients with a dilated ventricular system. However a normal echoencephalogram in paediatric patients is characterized by parenchymal echoes covering almost the whole recording therefore it is not necessary for diagnostic purposes, to obtain an *exact value of the lateral ventricle index in order to make sure* that the lateral ventricles are not dilated.

In patients with thicker skull bone the higher degree of absorption (cf p 17) *may cause the distal ventricle echo to disappear* but it *may* still be possible to obtain echoes from the proximal lateral ventricle. For compatible results, *it is necessary to use comparable surfaces since the echoes from* a concave and a convex surface of the same curvature differ somewhat (cf p 49)

On its pathway through the brain ultrasound passes through different tissues at somewhat varying speeds. However the differences in sound velocity in the brain (1515 m/sec) and cerebrospinal fluid (1504 m/sec) (cf p 14) are so small as to be negligible in an echoencephalogram a difference of less than 2/3 mm would be obtained if the skull cavity were full of cerebrospinal fluid instead of cerebral parenchyma.

A reflecting structure composed of several differently positioned components with acoustic properties differing from those of the environment, may give rise to a broad based multi peaked echo complex that is in such cases where

after a shunt operation, a constant value, or a decrease of the I value, indicates a well functioning shunt- an increase of I may be the first sign of an occlusion of the shunt (unpublished observations).

General considerations

Echoventriculography is an anatomical examination, similar in this respect to cerebral pneumography. From the primary results observed in the oscilloscope, the subsequent course of the examination is decided. For optimal results of this examination it should be performed, like pneumography by a physician who is experienced in the technical matters involved, has knowledge of the anatomy of the ventricular system and the physics of sound beams and is capable of three-dimensional conception.

Only in regions of the interfaces of the ventricular system which run parallel with the surface of the skull on which the plane probe surface is placed, can detailed echoencephalographic analysis be made this is a disadvantage of the echo method with the commercial echoencephalographic equipment available, since the probes are not especially adapted for studies of the ventricular system in infants. On the other hand, where ideal echoes are registered this method is one of high accuracy which allows fairly exact measures of the size of the lateral ventricles in physiological conditions.

VI. SUMMARY

The echoencephalographic examinations in this study were performed with a commercial echoencephalograph, which was found to be linear for the measurements in question.

Definitions

A method for ultrasonic A-scan examination with special regard to evaluation of the size of the ventricles in infants and small children is presented in detail such an examination has been called *echoventriculography* and the photographic recording of the results an *echoventriculogram (EVG)* An EVG comprises a midline control recording together with an echoencephalogram from the right and one from the left temporal region the position on the head at which the probe is placed in an EVG recording has been called the *test point* Closely occurring echoes of low amplitude which are recorded from the cerebral parenchyma have been designated *parenchymal echoes*

it. The index calculation gives a practical and precise expression of the size of the ventricles in relation to the actual diameter of the head, which is of especial value in paediatric practice with growing patients.

In addition this method of graphical representation gives an extra check with regard to the identification of the recorded echoes in cases where, for example both proximal and distal lateral ventricle echoes are obtained on the echoencephalograms from both the right and the left side, the proximal lateral ventricle echo from the right echoencephalogram will be on essentially the same vertical line in the diagram as the distal lateral ventricle echo from the echoencephalogram made from the left side.

Lateral ventricle index (I)

The index calculation means independence of the setting and calibration of the apparatus at the examination and permits direct comparison with, for example, cerebral pneumography without conversion of the width of the ventricles into ordinary units of measurement.

Furthermore, this method eliminates the sources of errors which a wide midline echo or variations in the breadths of the superficial structures, will produce when measuring the width of a lateral ventricle from the midline echo to the lateral ventricle echo or the parenchymal thickness from this echo to the bottom echo

The lateral ventricle index (I) is of especial value for follow up examinations of hydrocephalic infants.

For example, if an infant with hydrocephalus is examined on two different occasions, the lateral ventricles, in absolute measurements, may certainly show an enlargement, but on the other hand in relation to the cranial diameter on the second occasion they may be found to be relatively smaller than at the first examination so that in actual fact the hydrocephalic expansive process will have regressed

when one and the same value is obtained for I in an infant with a growing head at different times of examination it is clear that the hydrocephalic process is not progressing at the cost of the cerebral parenchyma—thus that the ventricles are growing only proportional to the cranial circumference—and there is usually no urgency for performing a shunt operation

on the contrary an increase of the value for I indicates an active hydrocephalic process with expansion of the ventricles at the cost of cerebral parenchyma this can be diagnosed—and a shunt operation performed—before any noteworthy increase in head circumference has been observed

In the examination liquid paraffin was used as contact medium between the probe and the surface of the head, thus allowing smooth movement of the probe along this surface. The layer of contact medium must be thin enough to be regarded as negligible when measuring the distances.

The patients were examined in the symmetrical horizontal position in echoencephalographic examinations of hydrocephalic patients, lateral deviation of both the lateral ventricle echo and the midline echo can be noted when the lateral position is used, compared with the supine position.

An echoencephalogram corresponding to the intracranial anatomical conditions can always be reproduced.

Using the above method, determination of the relative size of the lateral ventricles in infants with hydrocephalus can be performed with a standard deviation of 2 %, while for geometrical reasons associated with the beam, evaluation of the size of lateral ventricles of normal width is more approximate.

Completely *echo-free zones* which have remained echo-free even at maximal amplification of the apparatus, have been found, on comparison with the pneumogram to correspond to fluid filled intracranial spaces.

The name *lateral ventricle echo* has been given to the echo which laterally delimits an echo-free zone which in turn is medially divided by the midline echo

On reflection of ultrasound against a plane surface lying parallel to a plane probe surface, echoes of high amplitude are obtained, which rise practically at right angles to the time axis of the oscilloscopic tracing. Such echoes have been called *ideal echoes* only ideal echoes allow accurate distance evaluations Multiple, mutually confluent echoes of low amplitude are referred to collectively as *wide echoes* wide echoes may be due either to the properties of the reflecting structures or the geometry between the structures and the ultrasonic beam. Wide echoes *arising from faults or deficiencies in the technical procedure* of the examination have been called *artefact echoes*

Method

An echoencephalographic examination with special regard to the ventricular system consisted of the following stages

1) an orientational examination at which the oscilloscopic tracing was studied with regard to the overall impression individual echoes and echo-free zones, while the position of the probe was carefully varied over the respective test points, and while the amplification of the apparatus was also varied
2) recording of EVG when the tracing in the oscilloscope was reproducible in all respects
3) "scanning" over the patient's head (with the A scan equipment) while the oscilloscopic tracing was being studied, and also photographic recording of any noteworthy echoencephalograms from sites other than the test point, including a midline control from the same site,
4) preliminary interpretation of the EVG and any other recordings made at the examination and also any necessary complementary examinations in cases where the recordings were not representative of the overall picture in the oscilloscope,
5) measurement of the EVG and any paratemporal recordings graphical representation and calculation of indices,
6) summarizing evaluation with regard to the appearance of the ventricular system and any pathological conditions.

In the examination liquid paraffin was used as contact medium between the probe and the surface of the head, thus allowing smooth movement of the probe along this surface. The layer of contact medium must be thin enough to be regarded as negligible when measuring the distances.

The patients were examined in the symmetrical horizontal position; in echoencephalographic examinations of hydrocephalic patients, lateral deviation of both the lateral ventricle echo and the midline echo can be noted when the lateral position is used, compared with the supine position.

An echoencephalogram corresponding to the intracranial anatomical conditions can always be reproduced.

Using the above method, determination of the relative size of the lateral ventricles in infants with hydrocephalus can be performed with a standard deviation of 2 %, while for geometrical reasons associated with the beam, evaluation of the size of lateral ventricles of normal width is more approximate.

Completely *echo-free zones* which have remained echo-free even at maximal amplification of the apparatus, have been found on comparison with the pneumogram, to correspond to fluid filled intracranial spaces.

The name *lateral ventricle echo* has been given to the echo which laterally delimits an echo-free zone which in turn, is medially divided by the midline echo

On reflection of ultrasound against a plane surface lying parallel to a plane probe surface, echoes of high amplitude are obtained, which rise practically at right angles to the time axis of the oscilloscopic tracing Such echoes have been called *ideal echoes* only ideal echoes allow accurate distance evaluations. Multiple, mutually confluent echoes of low amplitude are referred to collectively as *wide echoes* wide echoes may be due either to the properties of the reflecting structures or the geometry between the structures and the ultrasonic beam Wide echoes arising from faults or deficiencies in the technical procedure of the examination have been called *artefact echoes*

Method

An echoencephalographic examination with special regard to the ventricular system consisted of the following stages

1) an orientational examination at which the oscilloscopic tracing was studied with regard to the overall impression individual echoes and echo-free zones, while the position of the probe was carefully varied over the respective test points, and while the amplification of the apparatus was also varied
2) recording of EVG when the tracing in the oscilloscope was reproducible in all respects,
3) "scanning over the patient's head (with the A scan equipment) while the oscilloscopic tracing was being studied, and also photographic recording of any noteworthy echoencephalograms from sites other than the test point, including a midline control from the same site,
4) preliminary interpretation of the EVG and any other recordings made at the examination and also any necessary complementary examinations in cases where the recordings were not representative of the overall picture in the oscilloscope
5) measurement of the EVG and any paratemporal recordings graphical representation and calculation of indices,
6) summarizing evaluation with regard to the appearance of the ventricular system and any pathological conditions.

GENERAL DISCUSSION

Physical calculations show how the potentialities of different ultrasonic frequencies for recording echoes from the interface between cerebrospinal fluid and brain parenchyma are influenced by the skull thickness (Fig. 2) they show further that on echoencephalography the orders of magnitude of the thermal, mechanical and molecular effects of the ultrasound are such that sufficiently broad margins exist before any injurious effects can occur and thus the method can be regarded as entirely harmless even for examinations of newborn babies.

With the ultrasonic echo method, exact determinations of distances are only possible under the condition that ideal echoes—which rise practically at right angles to the time axis of the oscilloscope—are obtained.

For physical reasons, ideal echoes are sometimes impossible to record from the intracranial structures of small infants, where echoes from, for example, the lateral wall of the lateral ventricle and sometimes also from the inner curved surface of the skull of the opposite side are not seldom combined with several small echoes arising from reflection against small surfaces at different distances from the probe.

Experimental investigations have shown, further that difficulties may be encountered in recording ideal echoes even on ultrasound reflection against a completely flat surface, if the probe is held against a curved surface with a small curvature radius, this means in clinical practice, for example, that technically it may be difficult to obtain ideal midline echoes in small infants even from a normal third ventricle situated at the midline. Consequently in infants it may be difficult and often impossible to record ideal echoes from any known intracranial structure which can constitute an exact reference point from which distances can be measured to echoes from other intracranial structures.

Therefore, in infants in whom ideal echoes have not been obtained, an echoencephalographic method which involves measurement between echoes from different intracranial structures—e.g. measurement of the width of the lateral ventricle as the distance between midline echo and lateral ventricle echo, or of the thickness of the cerebral parenchyma as the distance between lateral ventricle echo and bottom echo—will never give a reliable distance evaluation.

The echoencephalographic method presented in this study differs in principle

GENERAL DISCUSSION

Physical calculations show how the potentialities of different ultrasonic frequencies for recording echoes from the interface between cerebrospinal fluid and brain parenchyma are influenced by the skull thickness (Fig. 2) they show further that on echoencephalography the orders of magnitude of the thermal, mechanical and molecular effects of the ultrasound are such that sufficiently broad margins exist before any injurious effects can occur and thus the method can be regarded as entirely harmless even for examinations of newborn babies.

With the ultrasonic echo method, exact determinations of distances are only possible under the condition that ideal echoes—which rise practically at right angles to the time axis of the oscilloscope—are obtained.

For physical reasons, ideal echoes are sometimes impossible to record from the intracranial structures of small infants, where echoes from, for example, the lateral wall of the lateral ventricle and sometimes also from the inner curved surface of the skull of the opposite side are not seldom combined with several small echoes arising from reflection against small surfaces at different distances from the probe.

Experimental investigations have shown, further that difficulties may be encountered in recording ideal echoes even on ultrasound reflection against a completely flat surface, if the probe is held against a curved surface with a small curvature radius this means in clinical practice, for example, that technically it may be difficult to obtain ideal midline echoes in small infants even from a normal third ventricle situated at the midline. Consequently in infants it may be difficult and often impossible to record ideal echoes from any known intracranial structure which can constitute an exact reference point from which distances can be measured to echoes from other intracranial structures.

Therefore in infants in whom ideal echoes have not been obtained, an echoencephalographic method which involves measurement between echoes from different intracranial structures—e.g. measurement of the width of the lateral ventricle as the distance between midline echo and lateral ventricle echo, or of the thickness of the cerebral parenchyma as the distance between lateral ventricle echo and bottom echo—will never give a reliable distance evaluation.

The echoencephalographic method presented in this study differs in principle

GENERAL SUMMARY

Physical calculations indicate that the interface between cerebrospinal fluid and brain parenchyma can be recorded by echoencephalography under the condition that the thickness of the skull is 3 mm or less; they also indicate that the energy transferred during an echoencephalographic examination is considerably below the level at which harmful effects may occur, even in small infants.

An echoencephalographic method is presented, which was developed with especial regard to measurement of the ventricular size in infants and children, in whom, as a rule, multiple ideal intracranial echoes are not easily recordable; the measurements from the echoencephalograms are expressed, as indices, in relation to the diameter of the head, determinable precisely by an ultrasonic method, by means of a diagrammatic procedure which is simple to perform and not time consuming.

Methodological difficulties and sources of error apparent from experimental and clinical trials and physical calculations, and the way in which they could be eliminated, are discussed, as well as the advantages of expressing the ventricular size as an index in paediatric patients.

from the conventional procedure for evaluation of the echoencephalograms obtained, in that as a reference point in distance measurements the ultrasonically determined external diameter of the patient's head, which can be obtained exactly is used.

The measurement values obtained from the echoencephalograms are then expressed in relation to this diameter as indices (Fig 8) by means of a practical simple diagram procedure which takes little time. This means, firstly that conversion of the echoencephalographic measurement results to ordinary units of measurement, with possible enlargement of errors, is avoided, and secondly direct comparison of the results with those of other methods of examination, e.g cerebral pneumography becomes possible in infants with growing heads it is an advantage that the ventricular size is expressed in relation to the child's own cranial diameter

The lateral ventricle index (I) is of especial value for follow up examinations of hydrocephalic infants, where an increase of the I value will indicate an expansion of the ventricles at the cost of the cerebral parenchyma, and a decrease of the I value indicates a regression of the ventricular size (for example after an operation with a well functioning shunt) thus, the clinician can follow the actual hydrocephalic process quite independently of different cranial circumferences on different examination occasions.

Since the reference points—the outer demarcation points of the ultrasonically determined diameter of the head—are exact, then measurement to an ideal intracranial echo can also mean that this echoencephalographic method can be exact, e.g on evaluation of the size of the lateral ventricles in hydrocephalic children where the lateral walls of the lateral ventricles usually run parallel with the surface of the head and give rise to ideal echoes.

The definition of lateral ventricle echo in this study is that echo which laterally delimits an echo-free zone (from the intraventricular cerebrospinal fluid) which is divided medially by the midline echo For several reasons it has been found most suitable in determining the size of the lateral ventricles to make measurements to the distal lateral ventricle echo

In infants and children irregular echoes of low amplitude are recorded from the cerebral parenchyma an echo-free zone which remains echo-free even on maximal amplification of the apparatus thus implies a fluid filled space.

One further advantage in using the ultrasonically determined external diameter of the patient's head as reference is that echoencephalographic examinations can be made even in directions from which there are no definitely identifiable intracranial echoes of known location e.g along the longitudinal diameter of the head recordings of for example, echo-free zones in different projections of the head can therefore be evaluated and combined—in the same way as several photographs in a cerebral pneumography—to form a three-dimensional picture of the fluid filled spaces inside an infant's head.

GENERAL SUMMARY

Physical calculations indicate that the interface between cerebrospinal fluid and brain parenchyma can be recorded by echoencephalography under the condition that the thickness of the skull is 3 mm or less; they also indicate that the energy transferred during an echoencephalographic examination is considerably below the level at which harmful effects may occur even in small infants.

An echoencephalographic method is presented, which was developed with especial regard to measurement of the ventricular size in infants and children, in whom, as a rule, multiple ideal intracranial echoes are not easily recordable: the measurements from the echoencephalograms are expressed, as indices, in relation to the diameter of the head, determinable precisely by an ultrasonic method, by means of a diagrammatic procedure which is simple to perform and not time consuming.

Methodological difficulties and sources of error apparent from experimental and clinical trials and physical calculations, and the way in which they could be eliminated, are discussed, as well as the advantages of expressing the ventricular size as an index in paediatric patients.

from the conventional procedure for evaluation of the echoencephalograms obtained, in that as a reference point in distance measurements the ultrasonically determined external diameter of the patient's head, which can be obtained exactly is used.

The measurement values obtained from the echoencephalograms are then expressed in relation to this diameter as indices (Fig 8) by means of a practical simple diagram procedure which takes little time. This means, firstly that conversion of the echoencephalographic measurement results to ordinary units of measurement, with possible enlargement of errors, is avoided, and secondly direct comparison of the results with those of other methods of examination, e.g. cerebral pneumography becomes possible in infants with growing heads it is an advantage that the ventricular size is expressed in relation to the child's own cranial diameter

The lateral ventricle index (I) is of especial value for follow up examinations of hydrocephalic infants, where an increase of the I value will indicate an expansion of the ventricles at the cost of the cerebral parenchyma, and a decrease of the I value indicates a regression of the ventricular size (for example after an operation with a well functioning shunt) thus, the clinician can follow the actual hydrocephalic process quite independently of different cranial circumferences on different examination occasions.

Since the reference points—the outer demarcation points of the ultrasonically determined diameter of the head—are exact, then measurement to an ideal intracranial echo can also mean that this echoencephalographic method can be exact e.g on evaluation of the size of the lateral ventricles in hydrocephalic children where the lateral walls of the lateral ventricles usually run parallel with the surface of the head and give rise to ideal echoes.

The definition of lateral ventricle echo in this study is that echo which laterally delimits an echo-free zone (from the intraventricular cerebrospinal fluid) which is divided medially by the midline echo For several reasons it has been found most suitable in determining the size of the lateral ventricles to make measurements to the distal lateral ventricle echo

In infants and children irregular echoes of low amplitude are recorded from the cerebral parenchyma an echo-free zone which remains echo-free even on maximal amplification of the apparatus thus implies a fluid filled space.

One further advantage in using the ultrasonically determined external diameter of the patient's head as reference is that echoencephalographic examinations can be made even in directions from which there are no definitely identifiable intracranial echoes of known location e.g along the longitudinal diameter of the head recordings of for example, echo-free zones in different projections of the head can therefore be evaluated and combined—in the same way as several photographs in a cerebral pneumography—to form a three-dimensional picture of the fluid filled spaces inside an infant's head.

ACKNOWLEDGEMENTS

My work with echoencephalography in infants and children was carried out at the Department of Paediatrics, University Hospital, Uppsala, Sweden, under the general supervision of Professor Bo Vahlquist, the head of the Department. I am much indebted to him for his stimulating interest in my work.

My special thanks are due to my husband Håkan Sjögren, Assistant Professor at the Department of Physics at the Royal Institute of Technology Stockholm, who originally suggested this study and helped me to understand the physical properties of ultrasound and the echoencephalographic equipment, and for his valuable advice on the physical calculations.

Associate Professor Stig Jeppsson, head of the Department of Neurosurgery at the Regional Hospital, Linköping, has encouraged me in my work and taught me personally from his vast experience of echoencephalography I am deeply grateful to him for stimulating discussions and his positive criticism of this work.

My grateful thanks are also due to the paediatric neurologist, Associate Professor Bengt Hagberg, University Hospital, Uppsala, Associate Professor Lars Garby University Hospital, Uppsala, and Professor Helmuth Hertz at the Institute of Technology Lund, for their valuable discussions and criticism of the manuscript.

This work was made possible by grants from the Folke Bernadotte Foundation for Children with Cerebral Palsy the Bengt and Birgit Hedström Family Donation Fund, and from the Medical Faculty Uppsala University

PROCEEDINGS

OF THE

FIFTEENTH NORTHERN PEDIATRIC CONGRESS

Bergen, June 28—July 1 1967

ORGANIZING COMMITTEE

Alfred Sundal, president
Peter Johan Moe, secretary general
Dagfinn Aarskog
Arve Hesseberg
Johan Olsen
Per Erik Waaler
Karl Wilhelm Wefring

EXECUTIVE COUNCIL

Danish section

Povl Brastrup
Jørgen Flamand Christensen
Preben Plum
Henning Andersen, secretary

Finnish section

E. K. Ahvenainen
Ole Wasz-Höckert
Bernhard Landtman, secretary

Norwegian section

Arne Njå
Roald Rinvik
Alfred Sundal
Peter Johan Moe, secretary

Swedish section

John Lind
Bertil Lindquist
Rolf Zetterström
Carl Gustaf Bergstrand, secretary

ACTA PÆDIATRICA

SUPPLEMENT No. 177

List of Supplements to Acta Pædiatrica Scandinavica

1. Muhl, Greta, Über den Stoffwechsel des gesunden, natürlich ernährten Säuglings und dessen Beeinflussung durch Fettreduktion der Nahrung. Sw. kr. 5.—
2. Höjer, J. Axel, Studies in Scurvy. Sw. kr. 5.—
3. Eriksson, Zelda, Über Anstaltsschäden der Kinder (Hospitalismus) in Kinderheimen. Sw. kr. 1.—
4. Drucker, Paul, Clinical Investigations into the Pathogenesis of Infantile Tetany. Sw. kr. 1.—
5. Wallgren, Arvid, Contribution à l'étude des splénomégalies de l'enfance. Sw. kr. 5.—
6. Rhodin, Hans, The Suspension-Stability of the Blood in Scarlatina. Sw. kr. 1.—
7. *The proceedings of the Fourth Scandinavian Pediatric Congress.* Helsingfors, June 28–30, 1927. Sw. kr. 5.—

Presidential Address

ALFRED SUNDAL
Department of Pediatrics, University of Bergen

Ladies and Gentlemen

On behalf of the Congress Committee and of Norwegian pediatricians I take great pleasure in welcoming pediatricians from the five Northern countries to the XVth Northern Pediatric Congress.

I also welcome our guests of honour their presence at the opening of the Congress will lend lustre to our meeting to-day and to the work we are to do together in the course of the next few days.

The Northern Pediatric Association, an amalgamation of the national associations of pediatricians in the Nortern countries, has to-day nine honorary members. In giving them this special membership it has been our desire to honour the great contribution they have made to pediatrics as a whole and, in particular to the development of pediatrics in the North Unfortunately only one of these honorary members, Professor Arvid Wallgren, of Stockholm, is present to-day We have all the more reason to thank him for coming, and to pay tribute to him as a great representative of the pediatricians of the North. The other eight honorary members, who were unfortunately not able to attend the Congress, are the following

From Denmark
Dr med. Paul Drucker
Dr med. Carl Friderichsen,
from Finland
Professor Arvo Ylppö,
Professor Viljo Rantasalo,
from Sweden
Professor Curt Gyllenswärd
Professor Nils Malmberg,
and from Norway
Dr med Arthur Collett,
Dr med. Lauritz Stoltenberg

Professor Ylppö and Dr med. Friderichsen have sent us their greetings by telegram.

We have received financial help from various industrial circles, partly through commercial displays in the building here, and I should like to express our thanks for this assistance.

Since our last meeting, in Stockholm in 1964 we have heard with regret of the death of several of our members from the national associations of pediatricians.

Professor Toivo *Salmi* of Finland died on Whitsunday 1965 at the age of 63 A native of Viborg, Karelia, Professor Salmi studied under Arvo Ylppö. In 1937 he began lecturing in pediatrics at Helsinki University and in 1945 was appointed to the newly established chair of pediatrics at Åbo University He took an active part in research work, particularly into the problems of newly born and premature infants. Social pediatrics also had a great claim on his interest.

Arvo *Arvola* died in April, 1965, at

the age of 61 He was Chief Physician of the Children's Unit of the Kotka Municipal Hospital and for the last three years of his life was Deputy Superintendent of the Central Hospital in Tammerfors.

Vuokko *Lahtiperä* died in 1965 at the age of 56 He was Chief Physician of the Isolation Hospital in Tammerfors and Municipal Medical Officer of Åbo

The following deaths have occurred among our Swedish colleagues

Professor Sture *Siwe* of the University of Lund died in April 1966 at the age of 69 He began his study of pediatrics at the Children's Hospital in Lund under his predecessor Professor af Klercker In 1936 Sture Siwe was appointed Professor of Pediatrics at the University of Lund He had wide interests in the field but is best known for his work on child tuberculosis, rickets infantile tetanus, and mental health work for children Outside Scandinavia his name is best known in connection with reticulo-endotheliosis in children the Letterer Siwe's disease

Lars Nilsson Assistant Physician of the Gothenburg Children's Hospital died in 1966 at the age of 39 The year before his death he defended his thesis for the doctorate entitled Thyroid Enlargement in Adolescence

Professor Edgar *Mannheimer* lost his life in a traffic accident in Africa in April 1965 He had been a lecturer in pediatrics at the Karolinska Institute and has led the first cardiological unit for children in the North at Kronprinsessan Lovisas Children's Hospital in Stockholm During the years preceding his death he was Chief Physician and Professor at the Swedish Ethiopian Children's Hospital in Addis Ababa He was a warm hearted enthusiastic and generous person who will be deeply missed

Sven *Huldt* Chief Physician of the Isolation Hospital in Danderyd died in October 1965

Sarah *Gyllencreutz*, practising pediatrician and school doctor in Stockholm died in March of this year

The Norwegian pediatrician Johanna *Schram Anderssen* died in October 1966 at the age of 69 She had her private practice here in Bergen her native city where the work she carried out might serve as a model for that of a practising pediatrician and family doctor

I ask the audience to stand and to pay homage in silence to the memory of our dear colleagues The contributions they made in different fields of pediatrics were of great value to the children of Scandinavia, and to the credit of the pediatric profession

We have looked forward to to-day with a certain amount of anxiety We asked ourselves several questions Would our colleagues from the other countries of the North come to Bergen? Would there be many participants or few? Should we be able to make satisfactory arrangements for such a large congress? We have been pleasantly surprised by the large number of participants — we are about 500 all told — and you are the ones to be thanked for that The question

of whether we shall be able to do our part satisfactorily must be left open for the time being

The interest we all have in common is pediatrics. Pediatrics embraces the study of the healthy and the sick child, and has as its goal the improvement of child health and the prevention and cure of disease. Our Northern congresses have the following tasks and aims the communication of the results of research, the discussion of problems with colleagues working in similar fields, the exchange of information, and mutual inspiration. Our long-term objective is that of increasing our insight and knowledge so that we shall be better able to improve health, to prevent and cure disease, to help the children of the North and the children of the world.

Medical science rolls on and research is the salient word. Considerable work is needed if progress is to be made. It would not be worthy of a country that calls itself civilized to rest on its laurels, leaving the task of further development to other nations. We must take part, as far as our abilities and circumstances allow in the gigantic work which is to a particular degree our responsibility the health of our children and the health of the nation We must endeavour to lay stone upon stone in building the edifice of pediatrics.

We live in a quiet corner of the world where we enjoy a high standard of living, social security and the services of well trained medical personell and well equipped hospitals. It must be admitted that our children have an advantage compared with many others. But this is an advantage which bears with it an obligation We must all devote ourselves to the tasks which lie waiting for specialists in pediatrics research problems, practical work as pediatricians here in Scandinavia or in the developing countries. There are many possibilities open to us if we have our eyes open and the courage to take hold.

Pediatrics is expanding It is first and foremost during childhood, when the organism is in the growth and development period, that we can influence the individual in a favourable or unfavourable direction Here in the North preventive health work with children has borne rich fruits. Curative pediatrics has expanded considerably and is continuing to develop Our insight into the pathology of childhood has never been greater than to-day

But let us not congratulate ourselves too heartily To-day we can rejoice to see more and more conquests being made in medical and pediatric sectors, but these are only possible because those who have gone before have laid a firm foundation on which we could build We must not forget that there are many steps on the ladder of pediatrics that we have yet to climb

The scientific programme of this Congress deals with topical questions. The main themes to be considered are 1) Malabsorptive disorders in pediatrics, and 2) Growth disturbances. A round table conference will throw light on the important practical question of non-obstructive urinary tract infections in children. A

the age of 61 He was Chief Physician of the Children's Unit of the Kotka Municipal Hospital and for the last three years of his life was Deputy Superintendent of the Central Hospital in Tammerfors.

PAPERS

number of lectures are to be held on subjects other than the main themes already mentioned a total of 60 publications will be read in the course of these three days In addition there will be 28 scientific exhibitions, and these will also be of great value The scientific part of the programme will, taken all in all give a cross-section of to-day s pediatrics, and will throw light on new advances and current research.

I thank all the lecturers and exhibitors who are going to pass the results of their research on to us and inspire us to become better pediatricians.

In addition to the chairman for the main themes and the leader of the round table conference the executive council of the Northern Pediatric Association will suggest the following vice presidents

Professor Bo Vahlquist, Sweden.

Professor Ole Wasz Höckert, Finland

Chief Physician Jorgen Flamand Christensen Denmark

I trust and hope that the delegates to this Congress will gain professional enrichment and that meeting their colleagues here will prove inspiring, and will lead to the making of new contacts and new friends. With these words I hereby open the XVth Northern Pediatric Congress.

SESSION I

SUBJECT Malabsorptive Disorders in Pediatrics

CHAIRMAN Professor Bertil Lindquist

1 Physiology of Carbohydrate Digestion and Absorption

A. DAHLQVIST

Research Department of the Hospital and Department of Physiological Chemistry University of Lund

The carbohydrates in the food are mainly present as polysaccharides and disaccharides, which are hydrolyzed to monosaccharides by the enzymes in the digestive tract. The first step in the hydrolysis of polysaccharides, such as starch and glycogen, is rapidly effected by the α-amylase, secreted from the salivary and pancreatic glands. The di- and oligosaccharides formed, as well as the disaccharides present as such in the diet (e.g sucrose and lactose) are then split by the disaccharidases of the small intestine. These enzymes are not secreted, but act in the absorbing mucosal cells. The disaccharidases are localized in the superficial part of the mucosal cells, most probably in the "brush border" which has been shown both by histochemical staining methods and by in vitro incubation techniques. It is, however still a matter of dispute whether they are located on the surface of the cells, in direct contact with the lumen of the intestine, or inside a superficial cell membrane. A recent electron-microscopic study has indicated that the intestinal disaccharidases are present in small "knobs" located on the surface of the microvilli, but it remains to be demonstrated whether these structures consist of naked enzymes attached to the outside of the cell membrane or of folds of the membrane forming a kind of "ultra microvilli"

The specificity of the small-intestinal disaccharidases has been studied by several methods. Heat inactivation studies reveal that the maltase activity in the human small intestine is exerted by at least four different enzymes, maltase Ia, maltase Ib, maltase II and maltase III. The isomaltase activity appears to be caused by the same enzyme as *maltase Ia*, the sucrase by maltase Ib. In addition

2 Gastrointestinal Allergy

L. A. HANSON

Dept. of Pediatrics and Institute of Medical Microbiology
Dept. of Bacteriology University of Göteborg

Ab omnigeno panis esu abhorrere et nauseare coepit With these words Hertod in 1671 described the first case of gastrointestinal allergy with omiting and diarrhea provoked by bread. This case report was followed by many others, and by now practically every food has been incriminated as a possible cause of gastrointestinal allergy The hypersensitivity to cow's milk has been especially well studied and has contributed to our knowledge of the different clinical expressions of allergic reactions from the gastrointestinal tract.

The difficulty of reaching a conclusive diagnosis in these cases was early noticed The importance of a detailed history was stressed but a search was made to find further support for the diagnosis. During the years 1906–1908 the eosinofilia of allergic disorders was demonstrated locally in the intestine as well as in the stool. Already in 1912 Schloss succeeded in relating the gastrointestinal symptoms in a case of egg allergy to a positive skin test with a protein fractionated from ovomucoid He was also able to desensitize the patient with this protein

The usefulness of the skin test in the diagnosis of gastrointestinal allergy was a matter of debate during the following years. The relation between a positive skin test to a food constituent and a gastrointestinal hypersensitivity to the food is poor with various authors reporting a correlation between 20 to 70% usually around 50% This illustrates the limited value of the skin test in the diagnosis of gastrointestinal allergy

In 1927 Rowe introduced the elimination diet which has become an important tool for diagnosis, especially in combination with various provocation tests.

It would be provocative to state that this brief historical survey of gastrointestinal allergy also represents, to a considerable degree, the status of this field today A quotation from an American allergologist as late as 1948 All functional gastrointestinal disorders have an allergic cause" indicates, however that there would be some truth in such a statement. That the diagnostic difficulties still exist is made obvious by the editorial remark on a recent paper in New England Journal of Medicine noting that the diagnosis of gastrointestinal allergy in the cases studied in the criticized paper was only based on "soft deduction

In the etiology of human gastrointestinal allergy the delayed type of hypersensitivity has not yet been shown to play a role, whereas the immediate type of hypersensitivity most probably is an important mechanism.

there is, however, one trehalase and one lactase. Chromatographic studies have supported these results but sucrase and lactase are further subfractionated into two components each on Sephadex columns The two sucrase fractions have very similar properties and it is uncertain whether the two fractions really represent different enzymes. The two lactase fractions in contrast, show marked differences in their enzymatic properties. They also differ in localisation One of them seems to be located in the brush border of the mucosal epithelial cells, like the other disaccharidases while the other one is soluble in the cell cytoplasm, or possibly lysozomal In lactase deficiency only the first one is absent.

After completed hydrolysis of the ingested polysaccharides and disaccharides the carbohydrates are transported through the mucosa in the form of monosaccharides. Glucose and galactose are transported via a specific mechanism which has the characteristic that these two monosaccharides can be transported against a concentration gradient. For a long time it was believed that the glucose galactose transport involved a phosphorylation-dephosphorylation reaction but this theory has now been abandoned On the basis of newer research it has been concluded that glucose and galactose are transported into the mucosal cells via a membrane bound carrier which can only bind the sugars if it can simultaneously bind sodium ions. The carrier does not itself influence the flow direction but only facilitates diffusion across the membrane. The accumulation of the sugar is effected by the simultaneous action of an energy linked sodium pump present in all cells, which transports sodium out of the cell and thus maintains the low intracellular sodium concentration Although the carrier has not yet been isolated and characterized a large number of experiments support the validity of this theory for the active transport of glucose and galactose

Detailed reviews of the different aspects of carbohydrate digestion and absorption are found in references no 1–4

Chromatographic studies have supported these results, but sucrase and lactase are further subfractionated into two components each on Sephadex columns. The two sucrase fractions have very similar properties, and it is uncertain whether the two fractions really represent different enzymes. The two lactase fractions, in contrast, show marked differences in their enzymatic properties They also differ in localisation. One of them seems to be located in the brush border of the mucosal epithelial cells, like the other disaccharidases while the other one is soluble in the cell cytoplasm, or possibly lysozomal In lactase deficiency only the first one is absent

After completed hydrolysis of the ingested polysaccharides and disaccharides the carbohydrates are transported through the mucosa in the form of monosaccharides. Glucose and galactose are transported via a specific mechanism which has the characteristic that these two monosaccharides can be transported against a concentration gradient. For a long time it was believed that the glucose galactose transport involved a phosphorylation-dephosphorylation reaction, but this theory has now been abandoned On the basis of newer research it has been concluded that glucose and galactose are transported into the mucosal cells via a membrane bound carrier which can only bind the sugars if it can simultaneously bind sodium ions. The carrier does not itself influence the flow direction, but only facilitates diffusion across the membrane The accumulation of the sugar is effected by the simultaneous action of an energy linked sodium pump, present in all cells which transports sodium out of the cell and thus maintains the low intracellular sodium concentration Although the carrier has not yet been isolated and characterized, a large number of experiments support the validity of this theory for the active transport of glucose and galactose.

Detailed reviews of the different aspects of carbohydrate digestion and absorption are found in references no 1–4

3 Laboratory Diagnosis of Malabsorption

G. MEEUWISSE

Department of Pediatrics, University of Lund

Steatorrhea, an important though not invariable symptom in intestinal malabsorption and pancreatic insufficiency is present when on an average diet the total fat excretion (6) exceeds 5 g (from puberty and onwards 6 g) During infancy a maximum of 10 per cent of dietary fat should be excreted Turbidimetric measurement of lipemia after a cream meal is a useful method for quick estimation of fat absorption (3 4) Pancreatic insufficiency can be screened by measuring chymotrypsin activity in a random feces sample (5) Detection of cystic fibrosis by measuring sweat electrolytes (2, 7) is important. The normal concentration of Na^+ and Cl^- is below 60 mEq/L.

Deficient xylose absorption speaks in favor of malabsorption (e.g celiac disease) After 15 g D-xylose/ sq m. orally as a 10 per cent solution the blood xylose concentration should normally exceed 15 mg per cent after 30 min. and 25 mg per cent after 60 min., these being better criteria than the urinary xylose excretion.

In the author's material of confirmed cases of diseased small intestine (by jejunal histology) among other cases of suspected malabsorption, the xylose absorption test and the serum turbidity after a cream meal (1 g fat/kg) were usually both pathological, but sometimes only one of them. Steatorrhea was usually but not always present. Other investigators (8) also found a combination of different absorption tests (xylose, FIGLU fat excretion) to be more diagnostic than any single test.

Sugar malabsorption will be suspected when watery diarrhoea with a pH of the stool below 5 is present. Fecal lactic acid excretion will then probably be increased (normally around 100 mg/24 h. in breast-fed infants and below 2.. mg/24 h. in other children) Many infants with sugar malabsorption also have increased fecal sugar (above 0.25 per cent of wet weight) A simple ward test by Clinitest[R] has been proposed (1) However this method — like other reduction methods — does not reveal fecal sucrose in sucrose malabsorption. Oral sugar loads of 30–50 g/sq.m. or 2 g/kg should normally increase the blood sugar level by at least 20 mg per cent. Fructose loads may normally give a flat blood sugar curve.

Routine clinical tests for quantitative protein absorption are not available. In the malabsorption syndrome a low serum albumin may be due to malabsorption, but also to protein loss through the intestinal wall. This can be tested by several isotope methods (^{131}I albumin ^{131}I PVP ^{51}Cr albumin and ^{59}Fe-Imferon)

Hematological studies and other methods to reveal deficiency of iron, vit. B_{12} or folic acid may give addi-

In the latter type of allergic mechanism the allergen induces in certain most probably genetically disposed individuals the formation of reagins These cell fixed antibodies release the chemical mediators of the allergic symptoms on their reaction with the homologous allergen.

The constituents of our food get into close contact with immunocompetent cells in the gastrointestinal tract. This is well illustrated by the finding of Lippard et al from 1936 that up to 80% of infants still had antigenic milk proteins demonstrable in their blood after cow s milk feeding The appearance of these circulating antigens was soon followed by precipitating antibodies in a high frequency Using the immunofluorescence technique Heremans and his associates have recently shown the formation of antibodies to food proteins in plasma cells in local intestinal lymph glands from non allergic individuals This indicates a local gastrointestinal antibody response. According to recent experimentation this local antibody response is made up of γA globulins of a special secretory type. The importance of this is still under investigation From animal experiments by Farr and his associates it is obvious however that an antigen (bovine serum albumin) induces as strong an antibody response given orally as if given subcutaneously in oil or intravenously

Many types of antibodies to foods often in high frequency have been reported by several authors using methods such as precipitation and agglutination which detect regular antibodies and not reagins. Such antibodies have no etiological relationship to any hypersensitivity and are thus very useful in diagnostic work It is possible however that they may sometimes represent blocking antibodies instead which can give protection against the allergen reagin reaction

Simple and reliable methods to demonstrate the etiologically important reaginic antibodies should be diagnostically very helpful but such methods are not yet available. The skin test is based on the activity of skin fixed reagins but obviously the presence of such reagins is a poor indicator of the presence of symptom releasing reagins fixed to cells in the shock organ the gastrointestinal tract. The Prausnitz Küstner test, which demonstrates circulating reagins, also shows a rather poor relation to gastrointestinal allergy (Heiner et al.) Encouraging results have been reported however from direct provocation of the shock-organ by testing in the rectal mucosa or by giving the suspected allergen in contrast liquid followed by studies of the gastrointestinal changes by X ray

The clinical diagnosis of gastrointestinal allergy must still mainly rest on a detailed history followed by elimination and provocation tests which are time consuming and sometimes dangerous.

4 Histopathology of the Small Bowel in Malabsorption States

P KUITUNEN

Children's Hospital, University of Helsinki

Since 1962 small intestinal biopsies have been performed at the Children's Hospital University of Helsinki. The Brandborg Rubin multipurpose tube has been used in 56 biopsies, of which 46 were performed on children under 2 years and the Crosby Kugler capsule in 146 biopsies of which 100 were performed on children under 2 years Two perforations occurred, the one in a 10-year-old girl with the Brandborg Rubin multipurpose tube and the other in a 5-months-old boy with the Crosby Kugler capsule (port size 2.5 mm)

In studying the duodeno-jejunal mucosa the following criterions for the villous height were used a normal mucosa over 300μ, slight mucosal changes 250–300μ partial villous atrophy (PVA) 150–250μ, and subtotal villous atrophy (SVA) under 150μ. Atrophy of the small intestinal mucosa was as a rule associated with other changes such as flattening of villous epithelial cells, vacuolization

and "round" cell *infiltration* in the villous epithelium. The brush border and the basement *membrane* were indistinct. The crypts of Lieberkühn were very *often elongated*. In the lamina propria there was a lymphocytic, and sometimes *also a plasma cell* infiltration.

The *histopathological changes* in the duodeno-jejunal mucosa showed a good *correlation* with the *results* of absorption tests (the D-xylose excretion and the *faecal fat excretion*)

If the patients had been on an elimination diet *(cow's* milk free and/or gluten free diet) for a long time the correlation was less significant.

A normal small intestinal mucosa was found in patients without absorption defects and in secondary malabsorption syndrome (pancreatic insufficiency disaccharide malabsorption and after resection of a large portion of the small intestine)

Slight mucosal changes were seen in patients who had chronic or recurrent diarrhoea with transient absorption defects, and in patients who had chronic malabsorption syndromes of unknown aetiology

A partial or subtotal villous atrophy seems to indicate a primary malabsorption syndrome with gluten intolerance. Some of these patients were also intolerant to cow's milk. Intolerance of cow's milk only occurred *in isolated cases*.

The histopathological findings are summarized in table 1 Subtotal villous atrophy is patognomonic for *the primary* malabsorption syndrome (39 patients out of 41) and a partial *villous atrophy* almost patognomonic (8 patients out of 11) Slight mucosal changes are unspecific and seldom indicate the primary malabsorption syndrome. A normal duodeno-jejunal mucosa excludes the possibility of the primary malabsorption syndrome.

Specific treatment had a favourable effect on the histology of the small intestinal mucosa, but a normalization was seen only in very few cases during a follow-up time of 1/2—2½ years.

Specific changes in the small intestinal mucosa such as in Whipple's disease, intestinal lymphangiectasy and acanthocytosis were not seen in our series.

TABLE. Summary of Histopathological Findings in Various Clinical Groups.

	Duodenojejunal histology			
	Normal mucosa	Slight changes	Partial villous atrophy (PVA)	Subtotal villous atrophy (SVA)
Number of patients	28	13	11	41
Primary malabsorption syndrome	0	3	8	39
"Others"	9	9	3	2
Patients without absorption defects	17	1	0	0

Transient absorption defects

5 Malabsorption of Sugars

B. LINDQUIST

Department of Pediatrics, University of Lund

10 years ago Durand (Italy) described an infant with chronic diarrhoea which was probably due to an insufficient splitting of lactose A short time thereafter Holzel (England) and Weijers (Holland) reported cases of diarrhoea in infancy caused by deficiency of lactase and invertase respectively

Clinical forms Two types of sugar malabsorption are seen (1) Conditions due to deficiency of one or more intestinal disaccharidases (2) Conditions due to disturbance in the transport of monosaccharides across the intestinal mucosa. Of both types there exist primary (congenital) as well as secondary (acquired) forms (see table 1)

Clinical picture Disaccharide and monosaccharide malabsorption show the same clinical picture The reason for this is that the diet contains practically no free monosaccharides and furthermore that the disaccharides must be split into monosaccharides before they can be absorbed The main symptom is diarrhoea of osmotic and/or fermentative type. In the congenital forms the stools have a watery consistency and resemble urine The onset of symptoms depends on when the intolerant sugar is introduced in the diet e g in lactase deficiency symptoms start soon after the first feeding It should be noted that in the beginning the general condition is good, the children eat with good appetite Dehydration may thus be prevented for a long time. Sometimes a slight steatorrhoea is seen due to a shortening of the intestinal passage time. When the children grow older the symptoms have a tendency to subside. In the secondary (acquired) forms the diarrhoea is more moderate. Sometimes the disorder shows a subclinical picture diarrhoea is of minor importance and the only symptoms might be colic, meteorism and flatulence when the patient consumes too much carbohydrates.

Etiology The congenital forms are all probably hereditary disorders inherited in an autosomal recessive way Several cases in the same family are often seen e g in glucose galactose malabsorption In invertase-isomaltase deficiency a reduced enzyme activity has been demonstrated in the parents of the patients.

The acquired forms are probably secondary to unspecific lesions of the intestinal mucosa Secondary lactase deficiency may thus be sequelae to intestinal infections. The frequency of individuals with more or less marked lactase deficiency may in certain groups be as high as 10% or more.

The question has therefore been discussed of whether certain human beings, like many other species, lose their capacity of producing lactase

later on in life If the milk consumption is low there will not be any history of milk intolerance.

Diagnosis Sugar malabsorption is diagnosed in the following ways (1) Estimation of fecal sugar This may be used as a screening test in infancy Normally no sugar can be demonstrated in faeces. (2) Oral sugar loading tests with different mono- and disaccharides. Loading with the intolerant sugar will result in a flat blood curve. (3) Measurement of disaccharidase activity in biopsy specimens of the intestinal mucosa. (It should be noted that the histology is normal in the primary forms of sugar malabsorption.) (4) Intubation studies of intestinal absorption. This technique which permits a simultaneous measurement of the absorption rate of different sugars, is especially used for confirming the dignosis of glucose-galactose malabsorption.

TABLE I Clinical Forms of Sugar Malabsorption.

	Monosaccharide malabsorption	Disaccharide malabsorption
Primary (congenital) Forms	Glucose-galactose malabsorption	(Immaturity of lactase producing mechanism) Lack of lactase ("Alactasia") Severe lactose intolerance(?) Combined lack of invertase and isomaltase Combined lack of invertase, isomaltase and maltase(?)
Secondary (acquired) Forms	Monosaccharide malabsorption in young infants of unknown etiology Monosaccharide malabsorption in Celiac disease Mucoviscidosis Enteritis Malnutrition	Acquired lactase deficiency of unknow etiology Disaccharide deficiency in Celiac disease (Sprue) Mucoviscidosis Enteritis Kwashiorkor Malnutrition

5 Malabsorption of Sugars

B. LINDQUIST

Department of Pediatrics, University of Lund

10 years ago Durand (Italy) described an infant with chronic diarrhoea which was probably due to an insufficient splitting of lactose. A short time thereafter Holzel (England) and Weijers (Holland) reported cases of diarrhoea in infancy caused by deficiency of lactase and invertase respectively

Clinical forms Two types of sugar malabsorption are seen (1) Conditions due to deficiency of one or more intestinal disaccharidases (2) Conditions due to disturbance in the transport of monosaccharides across the intestinal mucosa. Of both types there exist primary (congenital) as well as secondary (acquired) forms (see table 1)

Clinical picture Disaccharide and monosaccharide malabsorption show the same clinical picture The reason for this is that the diet contains practically no free monosaccharides and furthermore that the disaccharides must be split into monosaccharides before they can be absorbed The main symptom is diarrhoea of osmotic and/or fermentative type. In the congenital forms the stools have a watery consistency and resemble urine The onset of symptoms depends on when the intolerant sugar is introduced in the diet e g in lactase deficiency symptoms start soon after the first feeding It should be noted that in the beginning the general condition is good the children eat with good appetite. The acquired forms are probably secondary to unspecific lesions of the intestinal mucosa. Secondary lactase deficiency may thus be sequelae to intestinal infections. The frequency of individuals with more or less marked lactase deficiency may in certain groups be as high as 10% or more

The question has therefore been discussed of whether certain human beings, like many other species, lose their capacity of producing lactase

the age of 7–10 months. The duration of intolerance to gluten is independent of the age. On the average clinically active intolerance lasts 6–12 months, but apparently latent intolerance may remain for life.

The theories which relate to the ethiopathogenesis of malabsorption syndrome with intolerances (celiac disease) are discussed. A hypothesis is presented that there is a primary process, which damages the intestinal mucosa, so that the toxic effect of the gluten-born peptides can act and destroy the structure of mucosa. Subsequently an immunological process against gluten also comes into being. The primary process may be cow's milk allergy, infection, or congenital defect, etc.

7 Dipeptidase Activity in Small Intestinal Mucosa in Patients with Gluten-Induced Enteropathy

T LINDBERG

Department of Physiological Chemistry and Department of Pediatrics, University of Lund

The intestinal dipeptidases constitute a group of enzymes in the intestinal mucosa which take part in the final digestion of the protein (for ref. see 1). The significance of the intestinal dipeptidases in various pathological conditions of the gastrointestinal tract is unknown. By a spektro-photometric assay method (2) the activities of nine different dipeptides in small intestinal biopsy specimens from about 120 patients (adults and children) with various gastrointestinal disorders have now been investigated.

The material includes three adults and four children with gluten-induced enteropathy. The results from the adults have been reported previously (3). The results from the children are given in fig. 1. In the children as well as in the adults the various dipeptidase activities were all significantly lower than those in a control group of nine adult patients with normal mucosa and normal fecal fat excretion.

When the patients were treated with gluten-free diet for some months all the activities increased, most of them approaching the level of those in the control group. The peptidyl-proline dipeptidase activities were, however still decreased.

6 Intolerance to Food Proteins in Malabsorption Syndrome

J K. VISAKORPI

Children's Hospital, University of Helsinki

1) Table 1 presents the incidence and type of gastrointestinal intolerance to food proteins in malabsorption syndrome, according to the series compiled in the Children's Hospital Helsinki (1)

Although eight of the 12 infants with intolerance to cow's milk were also intolerant to gluten in most of them the intolerance to cow's milk was primary Other types of intolerance have also been studied It appears that a patient with intolerance to cow's milk frequently has additional intolerances to many other foodstuffs, such as soya, eggs, meat etc The author has examined an infant with intolerance to cow's milk and beef It seems that gastrointestinal intolerances without malabsorption are rare. No intolerance was observed in 46 children with chronic diarrhoea without malabsorption

2) Diagnosis of intolerance No single test which shows intolerance is in existence The precipitins are unsuitable for this purpose. The only valid method is clinical study As a rule, an improvement in appetite and the cessation of vomiting are the first signs of effective elimination These changes occur 1–2 weeks after the start of elimination Diarrhoea subsides within 1–4 weeks and patients start to gain weight within 3–4 weeks. However absorption tests gave normal results after some months, and jejunal histology after some years. Intolerance may be confirmed by introducing provocation although this is not always necessary moreover it is troublesome, on occasion dangerous, and may provide the wrong result

Usually patients with intolerance to cow's milk rapidly reacted to provocation (in 2–4 hours) with vomiting and diarrhoea nevertheless, about 10–20% of these are slow reactors, which slowly evince symptoms after some weeks of feeding with cow's milk Patients with gluten intolerance usually reacted slowly Less than one half of the cases exhibited an acute reaction, and about 5% of the patients reacted with anaphylactic collapse.

The duration of intolerance to cow's milk is normally rather short, disappearing when the patients reach

TABLE 1 Incidence and Types of Intolerance in Malabsorption

	Infants	Children	Together
Intolerance to			
gluten	12	0	12
cow's milk	28	8	36
together	40	[illegible]	48 (57%)
No intolerance	15	2	17 (20%)

8 Serum Level of Gamma A Immunoglobulin in the Primary Malabsorption Syndrome (Coeliac Disease) in Children

P IMMONEN and J K. VISAKORPI

Children's Hospital University of Helsinki.

Immuno electrophoresis together with the quantitative immuno-diffusion method (1) has been applied in a study of the serum levels of gamma A, gamma G and gamma M immunoglobulins in a series of 126 infants and children suffering from prolonged diarrhoea (3 2)

Pronounced elevation of the gamma A level was encountered in 31 out

of 50 patients with primary malabsorption, and also in 9 out of 14 patients with chronic diarrhoea and malabsorption of unknown aetiology. Hypergamma-A-globulinaemia was infrequent in malabsorption due to defects of digestion, in the secondary malabsorption syndrome, and in patients with normal absorptive function.

It was observable that hypergamma A-globulinaemia was age-dependent in the whole series: it was most frequent, and relatively more marked, in young infants. This was the only immuno-globulin abnormality in more than half of the cases, and was found, together with a less marked increase of gamma-G, in many of the remainder. It displayed no quantitative correlation with the precipating antibodies to cow's milk and gluten. It was almost invariably associated with inflammatory and usually clearly atrophic changes of the duodeno-jejunal mucosa.

In the primary malabsorption syndrome, the level of gamma A closely followed the course of the dietary therapy. During initial treatment with elimination diet, the level of gamma A decreased rapidly and on the average normal levels were reached in 4 weeks. Gamma-A was always normal during prolonged, successful therapy with elimination diet. A re-elevation of the level of gamma-A often followed positive diagnostic provocation (4) with wheat or cow's milk. This was even apparent in the second week after the onset of the provocation; the highest values were observed after three weeks, irrespective of the time at which clinical intolerance became evident, and accordingly of the duration of the provocation. A follow up was made of nine patients on discontinuation of the gluten-free diet. In six of them a marked increase of gamma A occurred. These patients exhibited either no, or only slight, symptoms of intolerance and impairment in the absorption test results although the small intestinal mucosal atrophy was still severe in all five patients subjected to a biopsy.

These findings indicate that determination of the level of gamma A serves as an additional diagnostic test in the primary malabsorption syndrome and is also useful in evaluation of the effect of dietary therapy. The hypergamma A-globulinaemia seems to reflect the inflammatory process of the small intestinal mucosa.

10 Congenital Primary Hypomagnesemia, an Inborn Error of Metabolism?

D SKYBERG J H. STROMME, R. NESBAKKEN and K. HARNÆS

Department of Pediatrics, and Isotope Division, Department of Clinical Chemistry University of Oslo, Rikshospitalet.

Within the last years, three reports on diseased male infants demonstrating hypomagnesemia as a cardinal sign have appeared (1 2,3) The clinical pictures of these cases have been almost identical and quite similar to that of the male infant reported on here.

Our patient showed generalized tetanic convulsions at the age of four weeks possibly preceded by a period of latent tetany Hypocalcemia (2 6–2 9 mEq/l) and hypomagnesemia (0,5 mEq/l) were found The hypocalcemia was not corrected by calcium treatment alone but upon magnesium medication (initially parenterally later orally) a normalization of serum magnesium as well as of serum calcium occurred Simultaneously the tendency to tetanic convulsions disappeared After the correction there was no need for calcium supplement, but a discontinuation of the magnesium treatment led to a gradual fall in serum magnesium followed by a fall also in serum calcium On the continuous oral magnesium supplement (20 mEq per day) the child has been healthy and has developed normally during 12 months follow up.

In contrast to the three cases reported this one had initially a high serum inorganic phosphorus. Furthermore, repeated determinations of the acid phosphatase as well as the prostatic acid phosphatase in serum have given variable and occasionally very high values. The reason for this remains unexplained. Parathormone given twice while the child was hypomagnesemic and hypocalcemic produced hypercalcemia but no change in the serum magnesium.

As to the possible causes of the low serum magnesium, no underlying disease known to give symptomatic hypomagnesemia, such as gastro-intestinal

diseases, primary aldosteronism or malnutrition has been detected. The observation that the renal excretion of magnesium fell almost to zero (about 0.5 mEq in four days) during a hypomagnesemic period rules out renal leakage as the cause. In fact, studies with radioactive ^{28}magnesium, given orally as well as intravenously indicate that the defect is to be found in an impaired intestinal absorption of magnesium. No significant intestinal loss of endogenous magnesium could be demonstrated.

On the basis of these findings, it appears to us that the child suffers from a congenital selective malabsorption of magnesium. This seems to be a new clinical entity since four cases with almost identical symptomatology have now been reported on.

SESSION II

CHAIRMAN Jørgen Flamand Christensen Odense

11 A Syndrome with Pancreatic Achylia and Granulocytopenia

K. LAUNIALA, U FURUHJELM, L. HJELT and J K. VISAKORPI

Children's Hospital, University of Helsinki

Cystic fibrosis of the pancreas is the best known disease of the pancreas in childhood In 1964 Shwachman *et al* (2) and Bodian *et al* (1) described a syndrome with pancreatic exocrine insufficiency and hypoplastic bone marrow a disease clearly separable from cystic fibrosis

This is a report on the clinical data of six patients with this new syndrome treated at The Children's Hospital, University of Helsinki. Two of the six were siblings. There was a total of 16 children in the five families affected of these 16 six were diagnosed as having this syndrome four more probably had the disease and six were healthy All the parents were healthy

The patients were all admitted for the first time during infancy they had chronic diarrhoea with failure to thrive (2 patients) diarrhoea, failure to thrive and respiratory infections (3 patients) or respiratory infection only (1 patient) In all five patients absorption tests indicated a malabsorption state typical of pancreatic insufficiency faecal fat was markedly increased, and the xylose excretion test gave a normal finding In all cases, the sweat chlorides were normal. Two patients were subjected to peroral duodenojejunal biopsy (by the courtesy of Dr Kuitunen) and the mucosal histology was found to be normal Pancreatic enzymes in the duodenal fluid were examined in three cases and clearly reduced activities of the enzymes were found Chest x ray did not reveal any fibrotic changes All the patients had variable degrees of granulocytopenia (average 200—400 granulocytes/mm^3) and a clear shift to the left was discovered (mean lobe count 1 49—2 17) Four patients had mild normochromic anaemia. Three of the patients had thrombocyte counts over 150 000/mm^3 and three had counts between 100 000 and 150 000/mm^3 The bone marrow exhibited hypocellularity in two cases, and normo- or hypercellu

larity in four cases. A shift to the left in the myelopoesis was observed in four cases. During severe infections, the number of granulocytes clearly increased in three of the patients.

Two patients who were without infections are now 13 and 14 years old they have steatorrhea and granulocytopenia continuously and their growth is subnormal, but otherwise they are progressing satisfactorily. Four patients died in the hospital of pneumonia, carditis and pneumococcal septicaemia at the age of 6—10 months.

Autopsies on two patients revealed very marked pathological changes in the pancreas. The hypoplastic pancreatic tissue was widely separated by adipose tissue, and acinar cells were almost absent in the hole lobules. The excretory ducts constituted the only component of the exocrine pancreas. The most prominent component in the pancreatic tissue was the cells, of which the structure was largely reminiscent of the islets of Langerhans. The changes were similar but somewhat milder in the two other patients. Some acinar cells were also noticeable in the pancreas of those patients.

12 Neutropenia and Insufficiency of the Exocrine Pancreas

E. MÖLLER, P OLIN and R. ZETTERSTRÖM

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Karolinska Institutet, Stockholm

This condition was first described by Shwachman *et al* 1963 and has since then been reported by several groups. A review of three relevant materials (1 2 3) gives the following clinical manifestations of the syndrome.

The patients are usually presented during the first year of life, with either severe infections or failure to thrive. They have a variable neutropenia and diminished or lacking excretion of pancreas enzymes with secondary steatorrhea. In addition some patients show short stature, epiphyseal dysplasia or mental retardation. They have normal sweat electrolytes. In some cases siblings have the full syndrome or only neutropenia.

Two siblings (Case 1 and 2) and two unrelated patients (Case 3 and 4) are presented. They demonstrate the different clinical pictures that

can be encountered in connection with this syndrome Efforts have been made to find an immunological abnormality, as the variable or cyclic neutropenia in these patients, with or without pancreatic insufficiency could theoretically be caused by an autoantibody reacting with neutrophils In mouse experiments it was recently demonstrated that polysaccaride antigens from E. coli after a single antigen injection give rise to a cyclical formation of 19 S antibodies (4) Since human blood group antigens, which have been demonstrated on leucocytes, are polysaccarides (5) cyclical neutropenia might be caused by an antibody possibly of the 19 S type

In this communication findings demonstrating that there is in the sera from patients with the syndrome of neutropenia and pancreatic insufficiency cytotoxic antibodies directed against granulocytes

Methods

Granulocytes and lymfocytes were fractionated from blood according to the method of Coulson and Chalmers (6) The presence of cytotoxic antibodies in serum capable of lysing nucleated cells, was examined according to the Gorer and O Gorman technique (7)

Results

In sera from Case No 2 3 and 4 cytotoxicity directed against their own granulocytes but not their lymphocytes could be detected Sera from patients 3 and 4 were also cytotoxic against granulocytes from the father of Case 3 and the mother of Case It has not been possible to obta enough granulocytes from Case 1 perform adequate cytotoxicity tes

Discussion

The cytotoxic factor present in se from these patients is not yet ider tified It has yet to be proved th the factor is of antibody characte Currently sera is fractioned by Se phadex G—200 chromatography determine if the factor is present the gammaglobulin region and if can be characterized as of the 7 S o the 19 S type. Further studies hav to be performed to determine if th factor is of iso- or autoantibody typ We might further speculate that th cytotoxic factor might react wit other cells than granulocytes such a pancreas exocrine cells The familia incidence reported in the literatur and in our cases, as well as the find ings that the patients sera react wit some of their parents sera, suggest that this is a genetically determine disease.

ABBREVIATED CASE REPORTS

Case 1 2 5/12 year old boy presented at the age of 6 months with failure to thrive and recurrent otitis. Birth weight 2.400 g He is short, following the 3rd percentile. He has severe neutropenia and trombocytopenia. He has a moderate steatorrhea and lacks trypsin in the duodenal fluid. Sweat electrolytes are normal

Case 2. 11 11/12 year old sister of Case 1 presented with severe recurrent otitis from her second year Birth weight 2.400 g She is severely growth retarded — below the 3rd percentile Bone age is not proportionally retarded. Variable neutropenia is present. Duodenal trypsin, sweat electrolytes and chest X-ray are normal. She is slightly mentally retarded.

Case 3. 1 6/12 year old girl with recurrent otitis since the age of 11 months. Birth weight 3.070 g Her height is above the 50th percentile. She has a cyclical neutropenia with peaks of increasing neutrophiles every 16th day She has no clinical or laboratory findings suggesting pancreas insufficiency

Case 4 3 3/12 year old boy presented at the age of 9 months with severe recurrent otitis, once complicated by sepsis. Birth weight 3 760 g Present height is at the 50th percentile. He has a variable neutropenia. He has had periods of frequent loose stools. Pancreas studies have not yet been performed.

13 Intensive Care of Small Premature Infants, Indications and Results of Treatment

E. K. VAPAAVUORI and N G. R. RAIHA

University Children Hospital, Helsinki

Recent reports on intensive care and assisted ventilation of newborn infants include only a few cases of very small prematures. These infants, however are a high risk group with high mortality and with a high incidence of severe RDS The purpose of this paper is to present 56 small premature infants, treated in the Neonatal Intensive Care Unit of University Children's Hospital, Helsinki. All prematures with birth weight between 900

and 1500 g who were admitted to the hospital during the year 1966 are included in the present study

All infants were treated in incubators and skin temperature was maintained at 36 5 C. An umbilical artery was catheterized as soon as possible after admission Arterial pH PO_2 and PCO_2 were determined following a *10* minute period of breathing 90—100% oxygen and after that at frequent intervals. The inspired oxygen concentration was adjusted to maintain arterial PO_2 between 60 and 100 *mm of Hg* The umbilical vein was also catheterized to begin an intravenous early feeding with 10% glucose solution and to correct acidosis by infusing Na bicarbonate according to acid base status.

Intermittent positive pressure respiration (BENNETT respirator type PR I or manual ventilation) was started when 1 primary apnea or repeated apneic spells occurred or when 2 pH PO_2 and PCO_2 could not be maintained.

Of the total 56 cases represented in the table, 31 showed clinical *signs of* RDS and 22 out of the 24 infants requiring endotracheal intubation and assisted ventilation had symptoms of *severe RDS 18 of these* were treated for apnea. 8 were intubated immediately after birth and transferred to the hospital on manual ventilation All had Apgar scores less than 4 at 5 minutes and all expired In the remaining 7 cases the positive-pressure respiration was started when arterial PO_2 and PCO_2 could not be maintained by conservative therapy 4 of these infants survived in contrast to only one surviving of the 18 infants treated for apnea.

The primary cause of death, as demonstrated by gross and histological autopsy findings, was massive intracerebral hemorrhage in 10 of 21 expired cases, total atelectasis of the lungs and severe hyaline membrane disease in 7 pneumonia in 2 and pneumothorax in 2 cases

	Conservative treatment	Respirator treatment	Total
Survived	30	5	35
Expired	2	19	21
Total	32	24	56

The treatment in the two groups designated as "conservative or "respirator" treatment was similar except for the use of artificial ventilation.

14 The Metabolism of Albumin in Normal and Premature Children

P. A. KRASILNIKOFF

Dept. of Clinical Physiology and Dept. of Pediatrics, Glostrup Hospital, Copenhagen

The metabolism of albumin was investigated in 31 normal children (from 8 days to 13 years old) and in 10 prematures (weight-range 1900 to 2400 g) The results were compared to the findings in normal adults (4)

The metabolic studies were carried out with Behring Werke Human Albumin, trocken, reinst' which we labelled with ^{131}I by the iodine monochloride method of McFarlane (2) In order to block the thyroid gland daily doses of inactive iodide were given orally during the study Each subject received 0.2 μC per kg body-weight of (^{131}I) albumin intravenously The first plasma sample was taken 15 minutes after the intravenous injection, and subsequently plasma samples were taken daily for 10—24 days. The serum albumin concentration was determined immunochemically in each plasma sample by means of the radial diffusion method described by Mancini *et al.* (1) The turnover data were calculated by mathematical analysis of the plasma curve according to Nosslin (3) The final slope of the plasma curve was controlled by whole body counting

In prematures and infants the serum albumin concentration was lower and the plasma volume/kg body weight was higher than the corresponding values in bigger children and adults. The intravascular mass of albumin/kg body weight was of the same order of magnitude both in children and adults (c. 2g/kg) Consequently the low serum albumin concentration in the smallest children is merely due to dilution.

The fractional catabolic rate (per cent of intravascular albumin mass degraded per day) decreased from about 20% in the prematures to about 8.5 / in the bigger children and adults. Correspondingly the rate of synthesis was high in the prematures (c. 0.50g/kg/day) and infants (c. 0.32 g/kg/day) compared to the bigger children (c. 0 17 g/kg/day) and adults (c. 0 16 g/kg/day)

Finally a good linear correlation was found between the rate of synthesis (g/day) and body weight, regardless of age.

15 The Q—A_2 Interval during Exercise in Assessing Severity of Aortic Stenosis

F GYULAI and Z. WALSH

Department of Pediatrics, Karolinska Sjukhuset, Stockholm

The patient material consists of 8 controls (2 normal 6 with minimal right sided involvement) and 14 patients with congenital aortic valvular stenosis (5 with gradient < 35 mm Hg 7 with gradient > 35 mm Hg 2 with clinical findings of mild AS) Both selective angiocardiography and cardiac catheterization were performed in all except 2 of the cases. Recordings were taken from the right second intercostal space with a 4-channel jet writer at a paper speed of 100 mm/sec. at rest and during exercise on a bicycle ergometer with a gradually increasing work load until the pulse rate reached 170—180 beats/min Each Q—A_2 value was the mean of at least 5 determinations

Fig 1 shows that at rest (supine) there was no significant difference in duration of the interval plotted against heart rate in patients and controls. However throughout exercise (sitting) at a comparable increase in

The relationship between Q A2 time and heart rate at rest in supine position in children with cong aortic stenosis

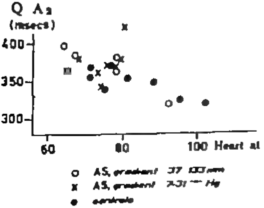

Fig 1

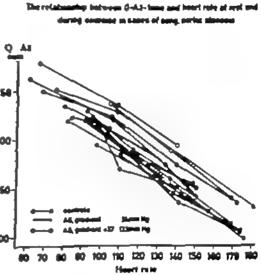

Fig 2

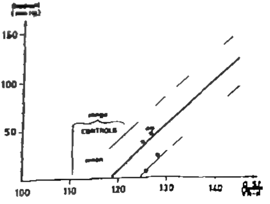

Fig 3.

heart rate, patients with more severe aortic stenosis had longer Q—A_2 intervals (Fig 2) This relationship was further demonstrated by the highly significant correlation found between the interval (corrected for heart rate) and the gradient across the aortic valve ($y = -562 + 4\ 75\ x$, $p < 0\ 001$) A similar relationship between the interval and left ventricular pressure was noted.

16 Deficiency of β-galactosidase and α-mannosidase — Primary Enzyme Defects in Gargoylism and a New Generalized Disease?

P A. ÖCKERMAN

Department of Physiological Chemistry University of Lund

It has been known for some time that mucopolysaccharides and gangliosides accumulate intracellularly in the lysosomes in patients with gargoylism. This storage may possibly be explained by a deficiency of a lysosomal enzyme, β-galactosidase. When the activity of several lysosomal acid hydrolases was measured in tissues, a deficiency of β-galactosidase was found in the liver skin and brain in patients with Hurler's syndrome and in the skin in patients with Hunter's syndrome Other lysosomal enzymes, including β-glucosidase, β-glucuronidase, N-acetylglucosaminidase, acid phosphatase, α-glucosidase, cathepsin C, α mannosidase α-fucosidase and β-xylosidase had a normal or higher than normal activity in the tissues. The deficiency of β-galactosidase did not seem to be due to the presence of an inhibitor

Increased activities of several acid hydrolases, including β-galactosidase, were found in the plasma in patients with Hurler's and Hunter's syndrome.

The possibility is discussed that there is a relationship between the low activity of β-galactosidase and the etiology of gargoylism.

A patient presenting a clinical picture resembling Hurler's syndrome was also studied. He had a marked tendency to infections, mental retardation, coarse traits, resembling Hurler's syndrome, hepato-splenomegaly gibbus, abnormality of the vertebrae, small grey patches on the capsule of the lens, hypogammaglobulinemia, vacuolized lymphocytes and storage cells in the bone marrow He died at the age of 4½ from an infection. Marked storage of a PAS-positive substance was found in the nervous system.

15 The Q—A₂ Interval during Exercise in Assessing Severity of Aortic Stenosis

F GYULAI and Z. WALSH

Department of Pediatrics, Karolinska Sjukhuset, Stockholm

The patient material consists of 8 controls (2 normal, 6 with minimal right sided involvement) and 14 patients with congenital aortic valvular stenosis (5 with gradient < 35 mm Hg 7 with gradient > 35 mm Hg 2 with clinical *findings of mild AS)* Both selective angiocardiography and cardiac catheterization were performed in all except 2 of the cases. Recordings were taken from the right second intercostal space with a 4-channel jet writer at a paper speed of 100 mm/sec. at rest and during exercise on a bicycle ergometer with a gradually increasing work load until the pulse rate reached 170—180 beats/min Each Q—A_2 value was the mean of at least 5 determinations.

18 The Diagnostic Value of Peripheral Venous Angiocardiography in Newborns and Young Infants

M. DAHL, L. HIRVONEN, E. KOIVISTO T PELTONEN and P VUORINEN

Children's Hospital and the Cardiorespiratory Research Unit of the University of Turku, and the Department of Radiology of the University of Oulu

Catheterization of the heart and intracardiac angiocardiography is not always possible in newborns and young infants. The authors have therefore studied the possibility and diagnostic value of peripheral venous angiocardiography in the diagnosis of congenital heart defects.

Peripheral venous angiocardiography was performed in 37 newborns and young infants. The contrast medium was injected into the vena premalleolaris.

In 27 cases the contrast was good and in 4 cases sufficient for a diagnosis. The failure in 6 cases at the beginning of the series was caused by various technical errors.

The contrast was good in the following cases 4 cases of ASD 11 cases of VSD 3 transpositions of the aorta, 3 coarctations of the oarta, 2 cases of pulmonary stenosis and 3 cases with a normal heart. The contrast was sufficient for the diagnosis in the following cases 3 cases of ASD and 1 case of VSD

A large transseptal shunt diminished the contrast considerably in some cases.

Peripheral venous angiocardiography can be recommended as a quick and comparatively reliable method for the examination of congenital heart defects in newborns and young infants, if catheterization of the heart or intracardial angiocardiography is not possible.

20 Premature Activation of Bilirubin UDP-Glucuronyl Transferase

A. F BAKKEN

Pediatric Research Institute, University of Oslo, Rikshospitalet

Conjugated bilirubin is normally not present in the serum of newborn infants. However in heavily Rh-immunized infants the presence of conjugated bilirubin ... veral times already at birth. This situation has been called obstructive jaundice in infants suffering from erythroblastosis foetalis. Evidence of ob-

This patient was found to have a storage of a mannose-containing substance, not yet characterized in the brain and the liver The activity of α mannosidase was low in the liver spleen and brain while several other lysosomal acid hydrolases were more active than in the controls.

The possibility is discussed that this patient represents a new disease with a deficiency of α mannosidase and consequent storage of a mannose containing compound

17 Nursing Ability of Norwegian Mothers

A. KÅSS

Department of Pediatrics, Vestfold Central Hospital, Tønsberg

At Vestfold Central Hospital we have examined the nursing ability of 2000 mothers of healthy full term babies When discharged from the obstetrical department 82% of the mothers gave full breast feeding 13 7% gave partial breast feeding whilst only 4 3% were discharged with artificial food for the baby

A follow up based on questionaries that also included various social information showed that the duration of the nursing ability was dishearteningly short.

Whilst more than 95% gave breast at their discharge this number fell to 50% already after 7 weeks 28% after 3 months and 12% after 6 months. Whilst 82% had full nursing ability at their discharge this number is reduced to 50% even before one month had gone and after 3 months only 15% of all mothers had full nursing ability Mothers who were discharged thus had only 50% chance of the same status after one month s time.

The duration of nursing showed no sure relationship to the mother s age or to the number of pregnancies On the other hand there seemed to be a slightly increased duration of the breast feeding in mothers from the countryside and in mothers from the financially best situated groups.

The material confirms the findings of other authors. The mothers of our time have good ability to establish breast feeding but a total lack of ability to keep up the good status promised by the amount of milk in the puerperium.

Should it be possible to expect improvement in this connection a radical change of opinion must occur with in all medical bodies and the public Measures that can be applied during pregnancy in puerperium at the obstetrical department, and during the critical period following discharge to the home, have been discussed

18. The Diagnostic Value of Peripheral Venous Angiocardiography in Newborns and Young Infants

M. DAHL, L. HIRVONEN E. KOIVISTO, T PELTONEN and P VUORINEN

Children's Hospital and the Cardiorespiratory Research Unit of the University of Turku, and the Department of Radiology of the University of Oulu

Catheterization of the heart and intracardiac angiocardiography is not always possible in newborns and young infants. The authors have therefore studied the possibility and diagnostic value of peripheral venous angiocardiography in the diagnosis of congenital heart defects.

Peripheral venous angiocardiography was performed in 37 newborns and young infants. The contrast medium was injected into the vena premalleolaris.

In 27 cases the contrast was good and in 4 cases sufficient for a diagnosis. The failure in 6 cases at the beginning of the series was caused by various technical errors.

The contrast was good in the following cases 4 cases of ASD 11 cases of VSD 3 transpositions of the aorta, 3 coarctations of the oarta, 2 cases of pulmonary stenosis and 3 cases with a normal heart. The contrast was sufficient for the diagnosis in the following cases 3 cases of ASD and 1 case of VSD

A large transseptal shunt diminished the contrast considerably in some cases.

Peripheral venous angiocardiography can be recommended as a quick and comparatively reliable method for the examination of congenital heart defects in newborns and young infants, if catheterization of the heart or intracardial angiocardiography is not possible.

20 Premature Activation of Bilirubin UDP Glucuronyl Transferase

A. F BAKKEN

Pediatric Research Institute, University of Oslo, Rikshospitalet

Conjugated bilirubin is normally not present in the serum of newborn infants. However in heavily Rh-immunized infants the presence of conjugated bilirubin has been found several times already at birth. This situation has been called obstructive jaundice in infants suffering from erythroblastosis foetalis. Evidence of obstruction besides the presence of con-

jugated bilirubin has not been found in these cases.

The existence of conjugated bili rubin in the serum of an infant is however primarily an indication of the bilirubin UDP glucuronyl tran ferase (BGT) being activated in the infant, as the conjugated bilirubin is unable to pass the placenta If conjugated bilirubin is present in an in fant at birth the BGT must have been activated prematurely

In cases of premature activation of the BGT the conjugated bilirubin will accumulate in the fetus and thus infant will present the symptoms of obstructive jaundice.

Infants suffering from erythroblastosis foetalis have been investigated It was found that the most immunized infants developed the ability to con jugate and excrete bilirubin earlier than the less immunized infants

Bilirubin itself was postulated to be the trigger of the BGT and the conjugated bilirubin to be the trigger of the capacity to excrete the bilirubin from the liver cell to the biliary capillaries

Three clinical groups were proposed

Group A Both the conjugating and the excretory capacities activ ated after birth (Normal and slightly immunized infants.)

Group B The conjugating capacity activated before birth and the excretory capacity activated after birth (Heavily immunized infants.)

Group C Both the conjugating and the excretory capacities activated before birth (Infants suffering from hydrops foetalis)

Pregnant rats were loaded with bilirubin and it was shown that the offspring of these rats were able to conjugate bilirubin at birth in con trast to normal newborn rats.

21 Globin as a Transport Protein for Bilirubin

J FOG E. KJELDSBERG and A. F BAKKEN

Pediatric Research Institute, University of Oslo, Rikshospitalet

In electrophoresis at pH 7 two yel low proteins have been observed in icteric sera from the newborn one which moves as bilirubin albumin and one which moves as a complex formed from bilirubin and globin This led to the assumption that globin acts as a transport protein for bili rubin

A colourless globin was prepared from hemoglobin and renatured as described by Lemberg and Legge (1) This globin contained traces of por phyrin and therefore, probably also

of iron. That the globin was in its native form was ascertained by adding alkaline hematine and sodium dithionite whereby the absorption curve of hemoglobin appeared. The absorption curve of oxyhemoglobin was registrable after oxygenation.

Alkaline bilirubin, added in excess to the globin and run on a Sephadex G-25 column with a phosphate buffer pH 6.2 (I 0.05) gave two yellow fractions, one nearly stationary due to free bilirubin and one which moved with the protein. The spectral absorption curve of the globin fraction was similar to the curve usually obtained with protein bonded bilirubin.

Electrophoresis was performed on strips of cellulose acetate and Krebs—Ringer's phosphate solution at pH 7.0. The anode was placed in pure phosphate buffer and linked to the system by cotton to avoid evolution of free chlorine. Icteric sera from cases of erythroblastosis and prematures which contained only unconjugated bilirubin, separated in two yellow fractions in this system, one which followed the albumin towards the anode and one which moved towards the cathode in the same way as bilirubin-globin formed in vitro. This yellow globin band was more pronounced in prematures. The albumin fraction reacted with diazotized sulphanilic acid while neither the cathodic fraction from icteric sera nor the complex formed from bilirubin and globin reacted on the strip even if it was treated with ethanol.

Globin would seem, taking into account its origin, and the above findings to function as a transport protein for bilirubin while the bilirubin albumin complex must be a store of bilirubin separated from globin but still unconjugated.

A bilirubin-iron-globin is a reasonable metabolite in hematoglobin degradation. A ring structure of the tetrapyrrol with the metal in the middle as in the structure given for the zinc biliverdin complex (2) and linked to the imidazol of the globin may explain why the complex fails to react with diazotized sulphanilic acid even in the presence of the usual accelerators.

22 Subsepsis Allergica Wissler

G BERGLUND and G WESSNER

Department of Pediatrics, Children's Hospital, Gothenburg

Subsepsis allergica or Wissler's syndrome is characterized by intermittent fever, exanthema, arthralgia, serositis, leucocytosis with eosinophilia.

The Children's Hospital in Gothenburg has during 1959—66 treated 12 patients with the diagnosis Wissler's syndrome. All were less than 10 years of age There were as many boys as girls

The first symptom in 9 cases was prolonged remittent fever in 3 cases combined with exanthema and arthralgia. The onset in 3 cases was insidious with diffuse joint symptoms and/or skin manifestations All patients had remittent fever and atypical exanthema during the course of the disease. 10 patients had joint symptoms, mostly short lasting and a few *had periarticular oedema. Serositis* developed in 5 usually pericarditis but also pleuritis and possible engagement of the peritoneum.

Laboratory findings high sedimentation rate, leucocytosis predominantly granulocytes but no eosinophilia The platelets showed high values in most cases. In some cases the number of platelets was correlated to the course of the disease Blood cultures were negative Antistreptolysin titre in 10 examined cases showed no increase. Antinuclear factor was negative in 8 cases examined Immunoglobulins examined in 3 cases were without changes Gammaglobulins were increased in 3 cases.

The 9 patients in whom fever was the dominating first symptom were first treated with antibiotics, without effect.

The joint symptoms were not influenced by salicylates or phenylbutazon.

Steroid treatment (prednisolon) gave an immediate effect in 11 patients, in a dose of 2—3 mg/kg body weight initially and with a slow decrease. If treatment was diminished too rapidly relapses occurred sometimes necessitating long treatment (more than 1 year) In 4 of these 6-merkaptopurine was tried with uncertain result.

Relapses appeared in a few cases several years after freedom from symptoms *without therapy The symptoms* were mainly the same as earlier but appeared to be less severe — possibly on account of more promply started therapy (prednisolon)

The prognosis is fairly good 1 patient expired 9 months after the onset of the disease, having received steroid treatment for 8 months At autopsy fresh bleedings in the adrenal cortex as well as chronical fibrotic pericarditis, slight diffuse interstitial fibrosis of the myocardium and pleuritis were shown No vasculitis or collagenosis was demonstrated

Differential diagnoses in high fe

brile cases were usually sepsis, osteomyelitis or febris rheumatica but the negative blood cultures, the lack of endocarditis and the negative antistreptolysin titre excluded these diagnoses. Those with dominating joint symptoms were difficult to distinguish from rheumatoid arthritis, but they demonstrated shifting polyarthritis, and no chronic changes or deformities developed.

SESSION III

CHAIRMAN Docent Jan Winberg Göteborg

23—31 Round Table Conference on Non Obstructive Urinary Tract Infections in Children

Participants H J ANDERSEN T BERGSTRÖM, L. Å. HANSON K. LINCOLN A. NYEGAARD F ORSKOV and I ØRSKOV

32—33 Free Lectures

Chairman Mr President esteemed collegues.

When discussing urinary tract infections (UTI) in childhood I think it may be wise to keep the following in mind We cannot disregard the possibility — not to say the probability — that many adults now straining our resources for chronic dialysis or renal transplantation have their renal damage as a consequence of renal infections during childhood. Our diagnostic and therapeutic possibilities as well as our knowledge of symptomatology have improved considerably during the later years. The doctor of today therefore has a much heavier responsibility for these patients than his somewhat older colleague who lacked many of today's facilities.

With regard to this we will concentrate the talk today on diagnosis, symptomatology and therapy As an illustration of this you will see here at the table three bacteriologists, two immunologists and three pediatricians. (The roentgenologist was alas unable to participate today)

In a stenciled paper that you will find on your desks we have tried to summarize our points of view upon the practical management of UTI and will let the discussion here be an illustration of that paper Dr Lincoln will first give you some bacteriological aspects.

K Lincoln To secure the diagnosis of urinary tract infection it is necessary to determine the species and the quantity of the infecting microorganisms. 262 first infections in girls were caused by *E coli* in 91 per cent, by *Klebsiella*, *Proteus* and *Pseudomonas* in 5 per cent and by enterococci in 1 per cent. In 81 recurrent non-obstructive infections in 20 girls the corresponding figures were 80 5 and 14 per cent. Thus bacterial etiology does not seem to be quite similar in first and recurrent infections.

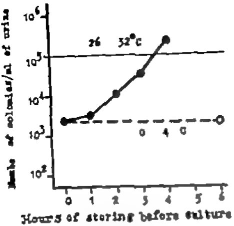

Fig. 1 Change of bacterial number of *E. coli* in urine stored at different temperatures.

stored at 26—37° C
stored at 0—4°C

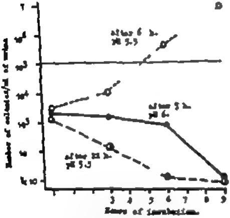

Fig. 2. Change of bacterial number of *E. coli* at 37° in three urine positions obtained at different times after single oral dose of shortacting sulphonamide (sulfisoxazole, GANTRISIN) of 50 mg/kg body weight. Even 22 hours after ingestion of this small dose urine contained enough sulphonamide to inhibit bacterial growth.

Urine obtained 5, 22 and 61 hours after ingestion of sulphonamide.

The figure of Edvard Kass from 1954 of 100 000 colonies per ml of urine is still valuable as a rough borderline between contamination and infection. We want again to emphasize the great importance of 1) proper cleaning before voiding, 2) immediate culture or cooled transport of the urine (Fig 1) and 3) the necessity of omitting therapy during a sufficiently long period before culture. (Fig 2) If quantitative culture is impossible, other methods of estimating bacterial quantity must be tried microscopy of stained smears of urine or chemical tests. In 222 urine samples from girls a tetrazolium test (Uroscreen) gave correct positive result in 79 per cent (69/88) and correct negative result in 89 per cent (119/134) when compared with 100.000 col/ml on quantitative culture.

As regards sulphonamide sensitivity we found in 237 first infections in girls that more than 90 per cent of the strains were sensitive. In 82 recurrences only 32 per cent were sensitive. It is thus impossible to generalize about the sensitivity pattern

The presence of pyuria was dependant on the clinical type of infection, see below

Chairman These things are simple but fundamental, and I will especially underline how erroneous it may be to cultivate urine not cooled during transportation.

E. coli is the dominating etiology in UTI. We know of the existence of enteropathogenic strains. Are there also special uropathogenic strains? This has been studied in a material of first infections in girls.

TABLE I

F og I Orskov (WHO International Escherichia Centre, Statens Serum institut, Copenhagen Denmark)

By biochemical and serological analysis it is possible to subdivide *E coli* strains into thousands of stable types.

The first and most simple step in this analysis is the determination of the 0 antigen 148 different *E. coli* antigens are known to-day Using antisera corresponding to these antigens, it is possible to determine the 0 group of 80—90 per cent of coli strains isolated from urinary tract infections. Some 0 groups (1 2 4 6 7 8 18, 75) are more common than others by the use of antisera corresponding to these eight antigens it is possible to determine the 0 group of 50—75 per cent of urinary strains Table I

With only few exceptions the same 0 groups are found to be frequent in urinary infections in different parts of the world Any coli 0 group can be found among sufficiently large numbers of urinary or faecal strains. Comparative investigations of faecal and urinary strains have shown that the same 0 groups are frequent in the intestine and in the urinary tract. At this juncture it should be stressed that too little is known about the distribution of *E coli* serotypes in the normal intestinal flora. Few if any of the hitherto published materials are quite satisfactory for a comparison between 0 group distribution among urinary strains and intestinal coli strains Nevertheless most investigators have found that the concentration of a limited number of 0 groups is greater in urine than in faeces, in other words it is possible by the use of the above mentioned eight 0 group antisera to determine the 0 group of a higher percentage of urinary strains than of faecal strains.

In Table I the result of a comparative investigation of urinary coli strains from first and recurrent infections in children is recorded For comparison the data from related in

vestigations in Scotland and USA have also been included. The Gote borg and the Scottish material both show a tendency to greater concentration of the 8 common 0 groups in the first infection material compared to the strains from recurrent infections. On the other hand, Kunin's examination does not show this tendency

We can conclude

1) The same coli 0 groups are common in urinary infections and in faeces, and the same common 0 groups are found in children and in adults.

2) The common coli 0 groups are found relatively more frequently among urinary strains than among faecal strains.

3) Some investigations — including the present one — show a tendency towards a greater concentration of these same 0 groups in first infection strains, compared to strains from recurrent infections.

4) Thus the situation is drastically different from that of the so-called enteropathogenic coli serotypes which are only found in children and primarily in sick children in children's institutions.

2 Calvin M Kunin, Robert Deutscher and Albert Paquin Urinary Tract Infection in School Children. An Epidemiological, Clinical and Laboratory Study *Medicine* 43 91 1964

Chairman Several investigations have demonstrated that only a minority of children hospitalised with UTI are referred with a correct diagnosis. Thus many doctors seem to be unfamiliar with the symptomatology A certain system in the variable clinical picture may be obtained by relating symptoms to such factors as sex, age, first infection or recurrent infection, which we will illustrate by three groups of patients.

T Bergström I will demonstrate some observations we made in girls aged 2 months — 16 years concerning the difference between first and recurrent infections.

There is a great risk of overlooking recurrences since they are often asymptomatic or give only vague symptoms. It seems as if the rate of asymptomatic infections is highest among the girls with many earlier infections. Thus, in a group of 100 girls with their first recurrence the ratio symptomatic to asymptomatic infections was 3:2 whereas in another group of 82 girls with repeated UTI the same ratio was 2:3

Further the urinary white cell count may be an unreliable diagnostic aid in recurrent infections. Whereas pyuria is found in almost 100 per cent of first infections it is often lacking in recurrent infections. Thus out of 130 recurrences caused by coliform bacteria only 2/3 had a urinary white cell count exceeding 50 cells per mm³ The corresponding figure for recurrences caused by enterococci was 1/3

Some doubt seems to exist about the danger of asymptomatic bacteriuria, especially when not combined

In Table 1 the result of a comparative investigation of urinary coli strains from first and recurrent infections in children is recorded For comparison the data from related in

with pyuria. But let us look at Figs. 3 A—C demonstrating the course of the disease in a girl followed from her first infection. In Fig. 3A only the symptomatic infections are presented and I do not think that many doctors would be alarmed by such a history. If the asymptomatic recurrences are added, Fig. 3 B, the situation appears a little more serious. The i.v. pyelography is plotted in Fig. 3 C and you should notice that scarring took place during a period dominated by asymptomatic recurrences. Such observations, which are not unique, underly our definite opinion that asymptomatic infections should be diagnosed and treated. Dr. Andersen will soon give you another illustrating example.

Chairman: From these observations we can thus conclude that the more frequent the recurrences, the more difficult the diagnosis — symptoms and white cells may disappear. A plausible explanation for this may be the development of tolerance to endotoxin.

Now over to nonobstructive UTI in boys, which is a rare disease after the first year of life — we found a sex ratio ♂/♀ of about 1/20. How do they appear clinically?

H. J. Andersen: We found 27 first or second infections in boys 4—15 years old. Some data are collected in Table 2.

It is obvious to anyone that this picture is not the same as that found in first infections of girls, and maybe the pathogenesis is also different? The relative infrequency of fever, of *E. coli* in the urine and the slow return of

TABLE 2

Some clinical characteristics of 27 boys aged 4—15 years with their first (22) or second (5) known UTI. No roentgenologically demonstrable obstruction.

Enterococci	3
Klebsiella	1

the concentration capacity to normal is suggestive of chronic pyelonephritis — using the word in its anatomical meaning. The parenchymal reduction demonstrated by x-ray in several of these patients may support this idea. So perhaps one should not mix boys and girls — at least not when discussing UTI.

Chairman: Neonatal infection is the third type of UTI which we want to discuss. From a study of 76 such infections (onset 0—30 days) not complicated by roentgenologically demonstrable malformations the following can be concluded:

Sluggishness, feeding difficulties, irritability, tenderness upon touching, poor gains in weight have been repeatedly described as leading symptoms.

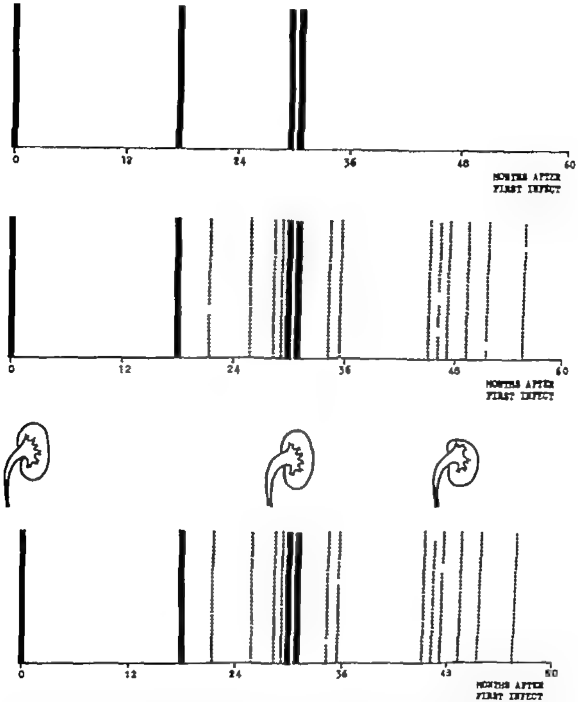

Fig 3 M.M. 540716 — a girl followed from her first known UTI at the age of 5 years
A. Only symptomatic infections plotted. This history does not seem especially alarming
B. The asymptomatic infections also plotted. The picture looks a little more serious. During the "free" interval between 36 and 46 months there was no check up, nor treatment.
C. Consecutive urographies show progressive scarring. This seemed to be especially rapid during a period dominated by asymptomatic infections.

Symptomatic infection

Asymptomatic infection

TABLE 3.

12.9	Neg	29	440	41	2^{15}
21.9			560	45	

Table 3 shows the application of these methods in a patient with an asymptomatic recurrence, with onset during hospital stay

Chairman This illustrates again that the asymptomatic infections may be severe and deserve our close attention. Check up cultures are necessary

Turning to the question of therapy it is essential to know the resistance pattern of the infecting bacteria. Again no generalized answers can be given — the resistance pattern varies among different patient groups. We can, however expect more than 90 per cent of first infections in girls to be sensitive to sulphonamide. Thus there is, for the moment, no reason to abandon this drug in first infections in girls. But for how long should the patients be treated?

T Bergström We treated 134 first infections in girls for 10 days and 103 for 60 days with Gantrisin, a short acting sulphonamide. A thorough follow up for one year showed a frequency of recurrence amounting to 33 per cent and 31 per cent respectively Thus nothing seems to be gained by extending therapy to 60 days in girls with first infections. This material will soon be published in detail (Acta Paediat Scand)

Chairman If we now turn our interest to the nature of recurring infections there are two possibilities either they are new infections, i.e. new invasions of the urinary tract, or they are recrudescences of an earlier defectively healed infection.

T Bergström We investigated this in 20 girls with 82 recurrences and found the frequency of new infection to be between 70 and 85 per cent. From this we can conclude that therapy had eradicated the infection in most instances, but failed to prevent new ones.

In patients with an established inclination to repeated infections long term *profylaxis* with a small dose of sulphonamide may reduce the frequency of recurrence. In contrast to this patients with a true chronic infection (i.e. bacteria persisting in the renal parenchyma) require high doses of bactericidal substances over long periods. These points of view are dealt with in *J Ped. 71* 13 1967

In children consecutive measurement of kidney growth is an indis-

This is true but in our experience other symptoms often triggered our attention towards the possibility of an UTI namely weight loss > 10% of body weight, a typical grey colour or cyanosis, distended abdomen simulating ileus and CNS symptoms not due to meningitis. It should be pointed out that fever and increased sedimentation rate was not a usual sign A positive blood culture was found in 50 per cent of those investigated markedly increased blood urea nitrogen in about 20 per cent. One third had massive reflux up into the calyces These infections seem to be as severe as they are difficult to diagnose Thus it was a not unusual experience that urine findings were negative for several days after the onset of symptoms

As you have noticed from the presentation of these three groups of patients the clinical picture and the laboratory findings vary with the type of the clinical material

The next speaker will touch upon some of the important urological aspects

A Nyegaard (in collaboration with T Gerts and M Eiken)
Since 1963 all children admitted to Gentofte Hospital with recurrent pyuriae have been included in a prospective study with special emphasis on radiography and surgical examination for evaluation of indications and results of operative treatment.

A preliminary report is given of the prevailing symptoms and results of long term medical treatment

Of a total of 66 children admitted in the years 1963 to 1966 19 were boys and 47 girls. Only 2 of the 26 children under 1 year had a completely normal X ray at the first examination 12 had hydronephrosis, 4 mega ureteres with reflux, and 3 had duplications in the urinary tract. A total of 16 of these children had various operations performed

Of 40 children more than 12 months old at first examination 19 had no abnormalities in the urinary tract. 7 had hydronephrosis, 4 mega ureteres and 3 had duplications in the urinary tract. 11 children had various corrective operations performed.

In follow up of these patients interest has been concentrated on whether the uretero-pelvic reflux could be secondary to urinary infections, in which case it would disappear during medical treatment of the pyuria. This seems to be the case in a few instances but the reverse causality seems to be the most common and at the time being a number of these patients have been re admitted for consideration of surgical measures against the reflux. The outcome will be reported when sufficient time has elapsed for evaluation of the results.

Chairman It seems reasonable to evaluate a pyelonephritis as a more severe infection than a cystitis. It is therefore a pertinent task to determine the anatomical location of the infection.

H J Andersen A description of two methods determination of renal concentration capacity and of the *E. coli* antibody titre, which both well serve this purpose has been published in detail (*Acta Paediat Scand 48* 318, 1959 *idem 54* 247 1965)

of existing methods for demonstration of bacteria by chemical methods.

Second Most recurrences in unobstructed infections are *not* due to inef fective treatment. Consequently interest should be directed more to better methods for profylaxis than to new ones for treatment. Long term check up is as essential as treatment of the acute infection.

Third Some patients develop a chronic disease others remain healthy as regards the kidneys. One of the most important goals for research now is to find methods by means of which those threatened by chronic disease can be recognized early For the moment it is for the sake of these relatively few that we have to check all patients for many years.

32 The Long Term Prognosis of Non-Obstructive Urinary Infection in Childhood

B. S. LINDBLAD and K. EKENGREN

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Stockholm

107 of the cases of children with non obstructive urinary infection, hospitalised during the years 1940—49 fulfilled the criteria of urinary in fection suggested by Steele *et al.* (1) 76 of the boys and 70% of the girls were reinvestigated.

At the time of reinvestigation the boys showed neither progressive renal disease in the form of parenchymal reduction nor infection and had not been treated for any urinary infection during the observation time.

Non-obstructive urinary infection in girls seems to be a potentially serious disease In spite of sulpha-treat ment late symptomatic recurrence had occurred in half of the cases. In 40% of the girls with late recurrence, or 19 % of the total, progressive upper urinary disease could be demonstrated Early recurrence, mentioned in the primary report, increased the risk of progressive renal disease from 4 to 30% After 20 years observation time, a single thorough clinical investigation, if negative, is not sufficient to evaluate the patient's condition. Besides repeated X ray investigation a thorough anamnesis seems to be of the greatest importance in the case of urinary infection in both children and adults.

It appears possible from the reinvestigation that maximal dehydration during pitressine load can provoke recurrence in recurrent or latent infections. In two additional cases, being treated in this clinic for recurrent infections from 6 months of age, it was

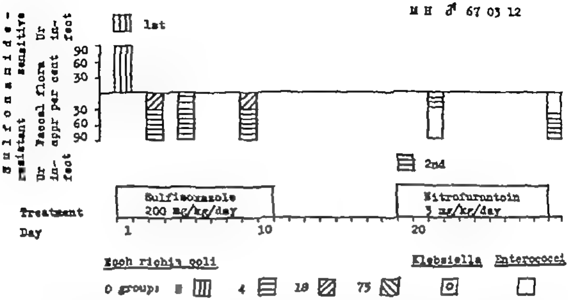

Fig 4 Change of aerobic faecal flora during oral sulphonamide (Gantrisin) treatment. The faecal flora was dominated by sulphonamide sensitive 02 at the first UTI During sulphonamide treatment there was a rapid change of the faecal flora. *E. coli* 02 vanished and sulphonamide-resistant 04 and 018 became dominant. When this patient got a recurrent infection at 19 days this was caused by the *E. coli* dominating at that time — namely sulphonamide-resistant 04

pensable method of ascertaining therapeutic effect (HODSON)

Chairman In one of our studies recurrences appearing immediately after the interruption of sulfonamide therapy were caused by sulphonamide resistant bacteria in 95 per cent (21/22 cases) The traditional evaluation is *defectively healed infections due to* selection of resistant strains in the urinary tract. But can we be sure of that?

K Lincoln (in collaboration with G Lidin Jansson) As most of the recurrent infections are true reinfections with new strains, the *site of development of resistance to* sulphonamide is probably not the urinary tract but rather the intestinal tract, see Fig 4

Chairman Finally we will discuss the situation where *we are* rather sure of a UTI but the urine findings are persistently negative.

H J Andersen Such situations may be the consequence of obstruction micro- or macroscopic, or presence of chemotherapeutic substances in the urine. Another possibility may be the occurrence of spheroplasts — *the cell wall-deficient forms of* bacteria. In these instances determination of the *E coli* antibody titre may be of diagnostic aid (cf *J Ped* 67 1080 1965)

Chairman Concluding this conversation I want to say the following *First* We have to sharpen our diagnostic accuracy as far as our resources permit Urine culture is the superior method for demonstration of bacteria, but for those who lack this possibility I will hope for a further improvement

of existing methods for demonstration of bacteria by chemical methods.

Second Most recurrences in unobstructed infections are *not* due to ineffective treatment. Consequently interest should be directed more to better methods for profylaxis than to new ones for treatment. Long term check up is as essential as treatment of the acute infection.

Third Some patients develop a chronic disease, others remain healthy as regards the kidneys. One of the most important goals for research now is to find methods by means of which those threatened by chronic disease can be recognized early. For the moment it is for the sake of these relatively few that we have to check all patients for many years.

32 The Long Term Prognosis of Non Obstructive Urinary Infection in Childhood

B. S. LINDBLAD and K. EKENGREN

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Stockholm

107 of the cases of children with non obstructive urinary infection, hospitalised during the years 1940—49 fulfilled the criteria of urinary infection suggested by Steele *et al.* (1) 76% of the boys and 70% of the girls were reinvestigated.

At the time of reinvestigation the boys showed neither progressive renal disease in the form of parenchymal reduction nor infection and had not been treated for any urinary infection during the observation time.

Non-obstructive urinary infection in girls seems to be a potentially serious disease. In spite of sulpha treatment late symptomatic recurrence had occurred in half of the cases. In 40% of the girls with late recurrence, or 19% of the total, progressive upper urinary disease could be demonstrated. Early recurrence, mentioned in the primary report, increased the risk of progressive renal disease from 4 to 30%. After 20 years observation time, a single thorough clinical investigation, if negative, is not sufficient to evaluate the patient's condition. Besides repeated X ray investigation a thorough anamnesis seems to be of the greatest importance in the case of urinary infection in both children and adults.

It appears possible from the reinvestigation that maximal dehydration during putrescine-load can provoke recurrence in recurrent or latent infections. In two additional cases, being treated in this clinic for recurrent infections from 6 months of age, it was

possible to provoke bacteriuria during maximal dehydration although there had been no symptoms and negative cultures for up to the previous 15 months. High diuresis during the treatment of acute pyelonephritis and a pitressine load in combination with urinary quantitative culture when checking the effect of the therapy is suggested

33 A Follow Up Study of 101 Patients with Infection of the Urinary System

(*Material stretching over a period of 5 years after 12—16 years of observation*)

T-O ENDSJØ

Department of Pediatrics, Ullevål Sykehus, Oslo

During the period 1950—1954 101 patients were hospitalised at the Children s Ward, Ullevål Hospital with different forms of infection of the urinary system. Of these 85 were girls and 16 boys. Most of them were treated with sulfonamides for 5—7 days, and a few for some time longer until their urine was normal. According to the present point of view the necessity for subsequent regular control was at that time not sufficiently emphasized

In 1966 a questionary was sent to each patient inquiring amongst other things whether the patient had had infections of the urinary system or other diseases of the urinary system All the patients filled out the questionaries. It appeared that 35 considered that they had later had a relapse of infection of the urinary system 66 considered that they had not had any infection of the urinary system after their first day at the ward On later examination it was seen that 4 of these had pyelonephritis.

Before their first hospitalisation, 58 children had had pyuria more than once. 28 were of the opinion that they had had infection of the urinary system during the period of observation 30 considered that they had suffered no relapse The follow up study showed that 3 of these had pyuria.

Of the 35 patients who according to the questionary considered that they had had infections of the urinary system during the observation period, 25 submitted to a follow up study The usual clinical tests were made urography and in about half the patients urethrocystography The tests

showed the following results X ray of 5 patients showed pyelonephritic changes, 5 had hydronephrosis, 1 patient had died on account of renal failure 2 years after the first hospitalisation in the ward. Follow up studies were also carried out on 14 patients who considered themselves as having been without relapse during the observation period 11 of these had recurrent pyuria before the first hospitalisation and 3 had malformations in the urinary system. Urography of the 3 patients with malformations showed pyelonephritic changes. One of these had pyelonephritic changes at the first examination One patient had clinical pyelonephritis and 10 patients showed no signs of infection of the urinary system. Of all the patients undergoing follow-up studies, it was considered necessary to hospitalise 10 for further investigation.

Urography was carried out on 87 children during their first stay in the ward. 62 of these had a normal urography 20 had malformations, 5 had hydronephrosis. Of the 14 patients who had not been tested with urography there were none who according to the questionary considered that *they had later had* a relapse of their infection of the urinary system. Out of 62 patients with normal urography at the first examination, 21 stated that they had later relapses of urinary system infection. Among the 20 children with malformations in the urinary system, 14 were found to have had relapses of urinary system infection Of 5 children with hydronephrosis, 2 were found to have had relapses.

Only 2 out of 9 patients with pyelonephritis and 5 with hydronephrosis had come for regular examination after their first hospitalisation in the ward. Considering these findings there is all reason to emphasize the necessity for regular control of children with malformations in the urinary system.

Even with one single attack of pyuria and normal urogram, the chances for relapse of infection of the urinary system seem to be so great, that there is all reason to convince both patient and parent of the importance of subsequent medical control.

SESSION IV

CHAIRMAN Ole Wasz Höckert, Uleåborg

---

34 Subnormal Concentration of Urinary Glucose as A Sign of Urinary Tract Infection in Children

B. SCHERSTÉN H FRITZ and L. KÖHLER

Department of Clinical Chemistry Department of Medical Microbiology and Department of Pediatrics, University Hospital of Lund

Urine from healthy fasting individuals contains small amounts of glucose. In adults the normal range has been found to vary from 2 to 20 mg/100 ml of urine A level below 2 mg/100 ml of urine was found to be a reliable indication of significant bacteriuria (1) This finding seemed to offer opportunities for mass screening for bacteriuria This communication reports the results from such a screening of 511 school girls aged 7—18 years.

METHODS

The children were instructed to empty their bladder on going to bed They were not allowed to eat anything after that time but were permitted to drink up to one glass of water during the night They were instructed not to urinate until the morning The urinary samples were collected as mid stream specimen from the first morning urine The samples were immediately chilled in a plastic ice bag and delivered to the school nurse in the morning The samples were sent to the laboratory for glucose determination and bacteriological culture The urinary glucose was determined by a fluorometric automated method using the fluorescence developed from $NADPH_2$ in relation to the amount of glucose in the sample in the presence of hexokinase glucose-6-phosphate dehydrogenase and NADP Significant bacteriuria was considered to be present when two or more samples collected consecutively showed growth of more than 100 000 organisms per ml of urine

RESULTS

Fig 1 shows a histogram of the urinary glucose concentrations found in 511 school girls.

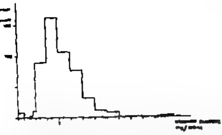

Fig 1 Distribution of urinary glucose concentration in 511 school girls 7 to 18 years of age.

In table 1 the correlation between urinary glucose and significant bacteriuria is evaluated. In eight girls there were less than 1 mg of glucose/100 ml of urine. Seven of these subjects had significant bacteriuria. The remaining subject showed no bacterial growth when cultures were made by routine method from two samples collected during a period of 3 weeks. When however cultures from the same samples were set up on a high osmotic medium, bacterial L-forms (protoplasts) were found. On subcultures these L-forms reverted to classical *E coli*

TABLE 1 Evaluation of subnormal levels of glucose in urine as sign of significant bacteriuria in 511 school girls.

[illegible]	Significant bacteriuria	No significant bacteriuria	Total number of cases
[illegible]			
[illegible]		503	503
[illegible]		[illegible]	511

x Including one subject with heavy growth of bacterial L-forms.

In the group of 503 subjects with more than 1 mg of glucose/100 ml of urine one girl had more than 100 000 *E. coli* in both samples collected These two samples, however had been collected in her chamber pot. The third sample, collected under appropriate conditions showed no bacterial growth. In the same group 10% of the girls had growth of 1 000—100,000 organisms per ml of urine. In

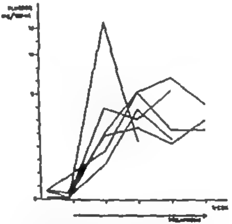

Fig. 2 Urinary glucose concentration before and after treatment in 6 subjects with significant bacteriuria. (In one of the subjects the second urinary glucose value before treatment is missing)

the second sample most of them showed no bacterial growth and still normal urinary glucose more than 100 000 organisms per ml of urine were not found in any one subject.

Fig 2 shows the effect of treatment on the urinary glucose concentration in six of the eight girls with significant bacteriuria. It may be seen that the normal range of glucose is found already in the sample collected after treatment for one week.

Thus the determination of urinary glucose seems to be a good screening method for significant bacteriuria as in this material all seven subjects with bacteriuria were detected Furthermore, one subject with bacterial L-forms was found None of the 503 subjects with normal urinary glucose had significant bacteriuria according to the criteria given

Mass screening for potentially serious diseases requires, however simple methods. For that reason we have developed a paper test sufficiently sensitive to react with the small amounts of glucose normally present in urine (2)

TABLE II Relation between colour reaction of test paper B and glucose content of 386 urinary samples.

Glucose content g/100 ml	Number of sample	TEST [illegible] REACTION AFTER [illegible]			
		No colour		++	+++
	2				
	8				
1					
3 [illegible]	[illegible]				
Total	386				[illegible]

In table II some of these results are summarized All 12 samples with less than 1 mg of glucose per 100 ml of urine gave no colour reaction with the test paper All these samples were collected from subjects with significant bacteriuria Out of the remaining 374 samples with more than 1 mg of glucose per 100 ml of urine and without significant bacteriuria, 2 gave no colour with the test paper and all the others a positive reaction for glucose Thus the sensitivity of the paper to detect significant bacteriuria was 100% and the specificity e.g the ability of the test paper to disclose non significant bacteriuria, was 99%

SUMMARY

In a material of 511 school girls 1.5% were found to have significant bacteriuria. All these cases could be detected by a sensitive automated fluorometric method for determination of urinary glucose as cases with significant bacteriuria have subnormal levels of urinary glucose (< 1 mg/100 ml) A glucose specific test paper is described, sufficiently sensitive to react with the small amounts of glucose normally present in urine The test paper can be used to discriminate between urinary samples containing less than, and those containing more than 1—1.5 mg of glucose per 100 ml of urine. Thus, the test paper may also be used as a screening method for significant bacteriuria.

35 Roentgenology and Micturition Dynamics of Infants with Urinary Tract Infections

K. HJALMÅS S. HAGBERG and H. LARSSON

Department of Radiology and Department of Pediatric Surgery University of Gothenburg

At the Clinic of Pediatric Surgery in Gothenburg we have made 150 simultaneous measurements of intravesical pressure and urine flow in children with recent urinary tract infections. 29 of the patients were infants. Our purpose has been to evaluate quantitatively an obstruction to flow suggested by the micturition urethrocystogram.

The material is chiefly composed of cases with urethral valves and bladder neck obstruction. In roentgenological terms, a valve means a distal urethral obstruction with distinct restriction of the lumen and change of urethral shape. In the bladder neck region, the obstruction is not so clearly defined. The anomaly of shape is expected to be of great importance as a cause of restriction to the urinary flow In the frontal and oblique as well as lateral projections there are sharp edges or bars in the bladder neck region instead of a flow promoting funnelshaped bladder urethra junction (Contraction coefficient) The enlargement of the diameter of a tube can increase the turbulence, thereby reducing the flow Other important factors are the length of the tube as well as the location of the obstruction in the proximal or distal urethra.

The intravesical pressure has been measured with a suprapubically introduced catheter in connection with a pressure transducer the urinary flow with a vertically mounted pressure transducer connected to an electronic derivator Pressure, flow urine volume, rectal pressure and detrusor pressure (rectal pressure subtracted from intravesical pressure) have been simultaneously recorded.

It is not possible to calculate correctly the minimal resistance to flow at a micturition because the urinary flow is laminar as well as turbulent in character We have been searching for an expression, called r with the same characteristics as resistance to flow So far we have been using the equation

$$r = \frac{P}{(Q\ k)^2}$$

where P is intravesical pressure, Q urinary flow and k a correction factor whereby flow is transformed to flow per square meter body surface area.

The following facts have been shown

1 Correlation between roentgenological and hydrodynamic evaluation is good.
2 In 6 cases, where the X ray films were suggestive of bladder neck ob-

struction, the pressure flow measurements yielded low (normal) values for r No operative procedures were performed in these cases. Further examination has shown the same or lower r values parallelling improvement of the roentgenological signs of obstruction.

36 Bacteriological Screening during the Neonatal Period

G BERGQVIST and J KJELLANDER

Department of Pediatrics and Department of Bacteriology Regional Hospital, Orebro

Infections are considered to be responsible for 10—20% of all perinatal mortality and currently afflict at least 1‰ of all newborn The symptoms of neonatal septicemia are diffuse which is probably one reason why the mortality rate is as high as 30—70% i.e about the same as from septic shock.

Neonatal septicemia, which appears during the first 72 hours of life, has normally been acquired before or during delivery and is caused principally by the coli group and by enterococci. Certain factors, such as a long time lapse between rupture of the amniotic membranes and partus, high temperature in the mother at delivery prem maturity and operations, increase the risk of infection Earlier investigators studied the relationship between infections in infants and positive blood cultures from the umbilical cord and histological changes in this If both of these factors existed a high percentage of the infants developed a septicemia. Infants with a positive blood culture from the umbilical cord have been reported to show signs of infection in 15% of cases, frequently containing the same bacteria strain

As this method seemed simple and not particularly laborious, we have cultured blood from the umbilical cord as a routine measure in all cases of complicated delivery in order to obtain a small risk group — subsequently thoroughly examined and when signs of infection were found treated according to the resistance pattern from the culture Early and adequate antibiotic treatment is effective in reducing the high mortality rate in neonatal septicemia.

From Oct 16, 1966 to May 31 1967 1 444 infants were born and in 160 cases blood cultures were taken from the umbilical cord The majority of the positive cases were regarded as contaminations as it is difficult to wash this region and contaminations are common even in normal delivery whereas staf aureus, e coli coliforms, enterococci, proteus and pseudomonas were regarded as suspectedly

pathogenic and the infants in these cases were reexamined with new blood cultures, quantitative urine cultures, throat cultures, micro-sedimentation rate and white cell blood count. Out of 20 infants thus examined, 3 had a clinical septicemia, although not verifiable upon cultivating check specimens. These infants were treated and survived. Three other infants had already received adequate prophylactic therapy.

This method appears valuable as a screening procedure, although we were unable to ascertain whether or not the strain found in blood from the umbilical cord is the same as that which produces symptoms.

39 Polyneuropathy in Children

I GAMSTORP

Department of Pediatrics, University Hospital, Lund

In the presented 42 children below 16 years of age impaired function could be demonstrated in at least two peripheral nerves The material was primarily divided according to the presence or absence of findings indicating involvement of the central nervous system also Thirteen children showed signs of such involvement whereas 28 appeared to have only peripheral neuropathy and in one case occurring in a newborn infant with severe muscular hypotonia and areflexia this point could not be settled

Among the 13 children with involvement also of the central nervous system two had late infantile metachromatic leucodystrophy one had a severe neurological complication to rubella with symptoms from the brain the spinal cord and the peripheral nerves, and two had Friedreich's ataxia. Several cases could not be assigned to any special group Three patients had an acute reversible disease reminiscent of a Guillain Barré syndrome, in two of them complicated only by definite reversible electroencephalographic abnormalities and in one by a severe brainstem involvement with unconsciousness lasting for three weeks. One boy had cerebellar ataxia and convulsions Another boy had a primary myopathy besides evidence of involvement of both the central and the peripheral nervous system. Three patients showed progressive symptoms, in two of them, two brothers the clinical picture was reminiscent of that described under the heading of chronic Wernicke-encephalopathy and in the third child clinical and laboratory findings were typical of Krabbe's disease.

Among the 28 children without signs of involvement of the central nervous system 11 had diabetes mellitus. These 11 were found among 107 unselected diabetic children who were studied in order to find the incidence of peripheral neuropathy in juvenile diabetes mellitus Two patients had a classical Guillain Barré syndrome A positive family history was recorded in 12 cases, occurring in eight different families The clinical picture varied in this group from minimal findings to severe, handicapping muscular weakness and wasting The findings in different affected members of the same family were similar whereas the variation was great between different families In three patients no explanation for the polyneuropathy could be found They all run a protracted course similar to that of the hereditary cases. In one of the unexplained cases the clinical findings were confined entirely to the right median nerve, but extensive neurophysiological examination revealed involvement of all examined peripheral nerves.

In the patients without involvement of the central nervous system the most common clinical findings were slow clumsy movements, muscular weakness and wasting, particularly of distal muscles, and hypoactive or absent muscle reflexes. Increased spinal fluid protein was seen in about half of the patients in whom this examination was performed. Decreased conduction velocity was noted in practically all the patients electro-myographical signs of denervation of distal muscles were seen in many of them.

40 The Librium Analogue Mogadon in the Treatment of Epilepsy in Children

B. HAGBERG

Department of Pediatrics, University Hospital, Uppsala

All diazepin derivatives in clinical use have some anticonvulsive properties. This also applies to chlordiazepoxide hydrochloride (Librium[R]) itself but its anticonvulsive effect is too limited to make it clinically useful. Valium[R] (7-chlor-benzodiazepin) has already gained a legitimate place as an antiepileptic drug of recognized importance, the main indication being all types of status epilepticus, where an intravenous injection of 2—10 mg in most cases gives a dramatic effect within one minute. The author has tried a third derivative, Mogadon (nitro-benzodiazepin) in 35 children with different types of minor fits which are often a much larger problem than major seizures.

The doses used in most cases ranged between 0.5—1.0 mg per kg body weight per day The tablets are of 5 mg each. Mogadon was found to be useful in more than half the cases with minor motor seizures (15 children) earlier resistant to numerous other anticonvulsants. Two infants with infantile spasms with no or only partial response to ACTH became quite free from seizures. Excellent results were also obtained in about one fourth of 15 cases with psychomotor epilepsy Some other cases benefited to a lesser degree. In the rest of the cases the effect was nil, or only transient. Two teen-age girls with a myoclonic type of genuine petit mal could be kept free from fits, while the result in 3 cases with the ordinary type of petit mal was poor

The side effect usually consisted of drowsiness, ataxia and the provocation of grand mal, the last mentioned occurring in 6 cases. Four children, three of them less than 3 years old, developed a rattling breathing with a marked bronchial hypersecretion. In a further two cases, a copious hypersalivation was observed, one of them also had increased lacrimation

about half an hour after each tablet of 5 mg A pronounced increase in appetite and weight was noted in 6 children One girl aged 14 attempted suicide after 17 tablets of Mogadon à 5 mg She developed severe ataxia, was drowsy and slightly confused, but her respiration was never depressed and she was all the time in a good general condition

41 Syndroma Gilles de la Tourette

V. KUMENTO and M.-L. KOSKI

Children's Hospital Turun Yliopisto

Gilles de la Tourette described in 1885 a syndrome starting in childhood and characterized by multiple motor tics coprolalia and often also by echolalia and echokinesis. The condition usually begins below the age of ten and is more common among boys than among girls The first symptoms are motor tics affecting the head face and neck The tics are violent in nature and noticed first when the patient is tired excited or under stress Gradually the symptom free intervals become shorter and the trunk muscles and legs become involved As the disease progresses vocal tics develop usually described as barking or grunting The last phase, which is said to be characteristic for the illness, is coprolalia utterance of obscenities Because of the often desperate outcome of the illness as well as the vigorous motor symptoms, many authors hold the opinion that the syndrome is based on a brain damage whose nature however is not known Symptomatic remissions, often on psychotherapy have been reported since 1940 Eisenberger Ascher and Kanner (1959) offered as their opinion that it seems justifiable to treat the patients psychotherapeutically Such treatment may at least be beneficial to the child and his family in overcoming the social handicaps brought about by the illness. In addition to this it is to be hoped that it may diminish the intrapsychic tensions which aggravate — if not cause — the symptoms.

Faux (1966) reported a case, whose complete recovery was attributed to three years treatment in a specific therapeutic hospital milieu where the patient in a new and meaningful way became able to comprehend some of the basic interpersonal problems.

Since 1961 a few cases have been published in which chlorpromazine seemed to alleviate symptoms and at least five cases have become symptom free on haloperidol

At the Pediatric Clinic of the University of Turku three cases of the syndrome under study have been found from 1965 to 1967 All are boys

from nine to twelve years of age. In one of the cases the prognosis seems to be very poor the patient cannot attend school, and repeatedly runs away and hides in the forests. His motor tics and echolalia are very prominent.

The second case is a boy of ten whose motor tics and loud shrieks had developed within the last year before admittance to the hospital. The boy had been under observation at a neurological ward, where his neurological examination and EEG were found to be normal. The boy is the youngest of five. His father is a jailer and his occupation may have coloured his opinions on bringing up children. The mother is a very submissive woman who tries to minimise the father's orders and prohibitions. Three of the boy's siblings have been antisocially disturbed. At the hospital the boy was first very restless and continuously uttering a loud "hah hah" This patient improved considerably in a pediatric ward where milieu therapy was given. The doctor (Dr Antti Kumento) who was in charge of the ward had a warm and acceptive relationship with the boy and this seemed to have a specific therapeutic value. *The boy's symptoms* first disappeared in situations where he experienced a safe feeling of being together with the doctor Behind the boy's restless and aggressive behaviour a strong need for tenderness was to be seen. As medicinal treatment the boy was given 30 mg Truxal daily His improvement has been sustained for at least half a year

The third patient is a boy of ten who developed symptoms typical of syndroma Gilles de la Tourette at the age of four after having been shut up in a dark wardrobe by mistake. At *the age of six, he had a symptom-free* interval for several weeks but his symptoms re-appeared after his mother went away for a two days trip This boy's symbiotic but aggressive clinging to his mother seems to be a central problem. In addition to these psychological problems the boy may be suffering from a brain damage caused by a long and difficult delivery His present neurological examination and EEG are normal but his psychological tests show disturbances characteristic of diffuse brain damage. The boy and his mother have been on out patient psychotherapy once a week for three months and the boy has been on haloperidol, 2 mg daily for two months. During the treatment his condition has improved considerably echolalia and coprolalia have disappeared and motor tics now appear in a very mild form.

The aetiology of Gilles de la Tourette's *syndrome* may be thought of as being multidimensional The organic and psychological factors form a spectrum of causation and their relative impact varies from case to case It is possibly that this condition is specifically connected with repressed aggressive emotions. The lessening of aggressions might lead to the disappearance of the symptoms. The improvement attributed to haloperidol may possibly also be connected with this, as haloperidol is usually indicated in aggressive, *manic* and psychomotor agitation.

44 Effect of Physical Training on School Children with Severe Motor Handicaps

B. EKBLOM and A. LUNDBERG

Adolescent Medical Department, Norrbackainstitutet and Department of Physiology Gym nastik och Idrottshögskolen, Stockholm

17 students at the Norrbacka Institute Schools. Cerebral palsy (CP) in 7 cases (median age 19 years) and para plegia from other causes than CP in 10 cases — mostly myelomeningocele — (median age 17 years) All students have severe motor — but not mental — handicaps and use wheel-chairs during their daily activities.

The students have been physically trained during 30 minutes twice a week for 6 weeks, parallel with the ordinary gymnastic lessons at school The training consisted of fast wheel chair driving raising and heaving up and down on the arms in the wheel chair and at the parallel bars, train ing with iron bars and heavy balls.

Submaximal work loads for all the students and maximal work loads for 8 non CP students were performed on an ergometer bicycle for arm work - Identical submaximal wor loads were performed before an after the training period togethe with determinations of oxygen uptake heart rate, blood lactate concentra tion and roentgenological heart vo lume.

A lower concentration of blood lac tate was found after the training in the CP group In the paraplegia group the oxygen uptake heart rate and blood lactate showed significantly lower values after the training In none of the groups could a change in heart volume be detected

The 8 students in the paraplegia group who could perform maximal work had increased this about 40% after the training

The better training results in the paraplegia group could be explained by the more severe handicap in the

CP-group, where also the arms were affected in most cases in contrast to the paraplegia-group The heart rate during training averaged 140 beats/min in the latter group but only 115 beats/min in the CP-group

The results show that these severely handicapped adolescents were capable of improving their working capacity in spite of the fact that the training was of rather mild intensity and performed during a relatively short period Thus, the ordinary gymnastic lessons seemed to be inadequate in order to improve the student's working capacity and should be changed to involve a training programme of the above described type. A higher working capacity is highly desirable for these students with regard to their performance in school and during their activities of daily living

It is concluded that this type of training should be included in the conventional habilitation programme for children and adolescents with motor handicaps of this type.

45 Infant Health Visitors as Collectors of Statistical Material

K. BIERING-SØRENSEN

The Municipal Agency of Infant Health Visitors in Copenhagen

The Danish public health visiting service, which was legalized 30 years ago is based on the infant health visitors going to the homes.

Thanks to this the health visitor contacts practically all homes having babies, notwithstanding the economical and social status of these and she will thus be able to make a personal contribution by collecting statistical material to form an estimate of the normal child's growth and development, or by registering the presence of various abnormal conditions among the children.

As the health visitor goes to practically all homes with babies the investigations are not beset with the same uncertainty as if only a certain section of the population had been under consideration.

Besides this, the training and social attitude of the health visitors gives them the best opportunity of avoiding a merely schematic conception, as for instance the evaluation of housing conditions solely according to the number of rooms etc.

In this connection it is of value to know that the health visitor thanks to the natural relationship of trust between her and the mother will be able to obtain far more reliable information than for instance professional interviewers would procure. In fact several of the investigations would

hardly have been practicable without the assistance of the health visitors.

In order to obtain as correct information as possible the health visitor's observations in the home are supplemented by information from hospitals or out patients clinics where the children have been examined, just as in cases of death of children information is obtained from a post mortem examination, if this is conducted

When health visitors assist in special research programs questionnaires or case records are made for the purpose

Finally the health visitor can in certain cases assist in actual experiments, just as the information on the standard sheet can serve as a source for comparative follow up-examinations, for instance, when the child reaches school age.

Reliable results of statistical research however depend on careful consideration of a lot of factors, not only during preliminary and statistical operations, but also in the final clinical — statistical evaluation of results.

As conclusions could be stated

1) The material must be as comprehensive as possible so that random variations will not have a decisive influence on results.

2) The material ought to be representative, and if it only comprises parts of a population-group the selection must be made in such a way that it is a completely casual section a random sample

3) The desired information must be tabled in well-defined groups, and the person taking down the information must be carefully instructed in order to avoid wrong classifications.

4) The information ought, when possible, to be supplemented from other sources, for instance by information from hospitals, etc.

5) In statistical research work there must be a close collaboration between the doctor and the statistician to avoid untenable or even directly wrong conclusions.

48 On Human Growth Hormone

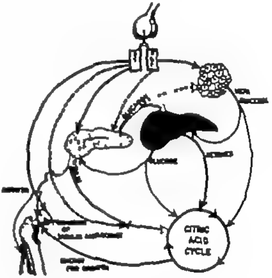
O TRYGSTAD

Pediatric Research Institute, University of Oslo, Rikshospitalet

Human growth hormone prepared according to the method of *Roos et al* (5) (here called HGH) had somatotrophic activity and a potent adipotrophic, hypocalcaemic and hyper glycaemic effect in rabbits Removal of a lipid mobilizing factor (LMF) from the crude human pituitary ex tract before preparation of growth hormone yielded a more homogene ous somatotrophic hormone (STH) On a per weight basis the somatotrophic activity of STH was about 25% higher than that of HGH The lipotrophic effect of STH was negli gible and it had no hypocalcaemic or hyperglycaemic effect in rabbits (6) The LMF was a potent adipotrophin in the rabbit and in man in rabbits it induced a prolonged hypergly caemia and a hypocalcaemia, with convulsions and death following big doses (7)

Ultracentrifugation studies demon strated that HGH is a mixture of STH and a lipid mobilizing fraction the molecular weight of STH being calculated to be about 18 900 (1) while *Li et al* (3) gave a molecular weight of 21 500 for human growth hormone Subcutaneous injection of 5 mg STH into 6 rabbits gave a mean increase of serum non-esterified fatty acids of $0\ 55 \pm 0\ 03$ meq/l ($\pm$ s e) while 5 mg hydrolyzed STH into 3 rabbits gave a mean increase of 1 54 $\times 0\ 05$ meq/l *Laron* (2) observed in creased in vitro lipolytic effect of STH after proteolysis

A dualistic effect of growth hor mone was discussed designated somatotrophic hormone (STH) and pituitary diabetogenic factor (PDF) in the Figure.



The LMF has no somatotrophic activity either biologically or im munologically (7) and immunization of rabbits has not produced LMF antibodies. However the immuniza tion produced a potent STH anti serum (4)

It was suggested that a lipotrophic core might be built into the amino acid-chain which forms the growth hormone similar to a MSH which forms a part of the ACTH-chain Pi tuitary enzyme systems may split off this core or the whole growth hor

mone depending on the demand of the organism. If this core is antigenic, it yields a good explanation of the observed increase of growth hormone in adult serum during variations in stress and in requirements for energy from fat depots. The LMF may itself be a new pituitary adipotrophin.

49 Chromosomal Abnormalities and Short Stature in Gonadal Dysgenesis

D. AARSKOG

Department of Pediatrics, University of Bergen

In 1954 different groups of workers demonstrated that the majority of patients with Turner's syndrome were sex chromatin negative, and in 1959 Ford and his coworkers (1) reported X-*chromosome monosomy* in such a patient. Recent cytogenetic findings have brought about a redefinition of Turner's syndrome as a syndrome of X-chromosome monosomy or partial monosomy with subsequent gonadal dysgenesis. Short stature is the most constant clinical finding in Turner's syndrome. The other somatic abnormalities might be present to a various extent, but might also be completely absent. The absence, or presence in only a slight degree, of phenotypic manifestations has especially been noted in cases where the X monosomy has been present in mosaicism, but is also now and then seen in cases with clear cut X *monosomy*.

In attempts to correlate the clinical to the cytogenetic findings cases with structural anomalies on the X-chromosome have been especially informative. These structural anomalies in

clude X isochromosomy for either the long or the short arm deletions of the long or the short arm of the X chromosome, and mosaics with these anomalies in one of the cell lines. Based on the findings in own and published cases with such structural anomalies Ferguson–Smith and co-workers (2) have concluded that the short stature and other somatic effects of Turner's syndrome can be produced by the loss however caused of the short arm of the X-chromosome only whereas the gonadal dysgenesis can be produced by the loss of either arm The findings in patients with deletions of the X-chromosome without mosaicism have particular significance in testing the validity of these conclusions. However such cases are rare, and hitherto only one patient has been reported with deletion the short arm (3) and a total of cases in which the deletion involv the long arm (4 5 6)

Two additional patients are repor ed one had a deletion involving t short arm of the X-chromosome ar the other a deleted long arm In bot patients the clinical findings were agreement with those expected accor ing to the hypothesis of Ferguson-Smith *et al*

Case I X. G J The patient was first se at the age of 14 years because of short statur The pregnancy was uneventful and she w born at term. The birth weight was abo 2000 g. Her motor and mental developme were normal. Although her general healt was good, she showed slow weight gain an linear growth from birth.

Her height was 132 cm (15 cm below 2.5 percentile) and her weight was 39 4 kg (3.

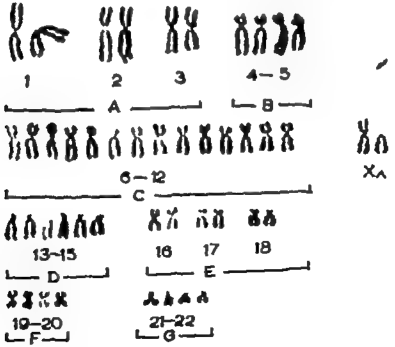

Fig 1 Karyotype analysis in case 1 showing a deletion of the short arm of one X-chromosome.

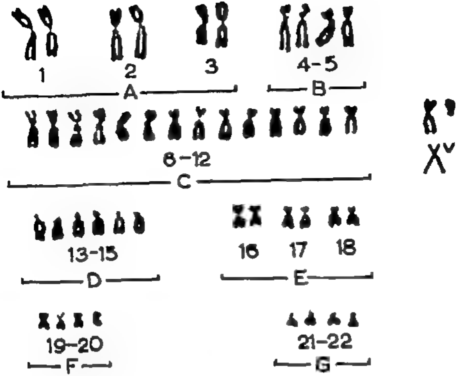

Fig. 2. Karyotype analysis in case 2 showing a probable deletion of the long arm of one X-chromosome.

kg above 97.5th-percentile). Her body build was rather stocky but the proportions corresponded to the chronological age. The neck was short, without webbing. There was bilateral cubitus valgus. The breasts were infantile with widely spaced nipples. Axillary hair was absent and pubic hair very sparse. Gynaecological examination revealed infantile female external genitalia. The uterus was small and ovaries were not felt. Exploratory laparotomy revealed bilateral streak gonads. The gonadotropin excretion in the urine was less than [illegible] M.U. per 24 hours.

Cytogenetic investigations. Buccal and vaginal smears revealed 10–12 per cent sex chromatin positive cells, but it was noted that the sex chromatin body was smaller than usual. Chromosomal analysis was carried out in cultured leucocytes from peripheral blood. A total of 90 metaphases were examined. Eighty six contained 46 chromosomes. Twenty of these cells were analysed in detail. In each instance the karyotype contained only 15 chromosomes in the C group and 7 chromosomes in the D group (Fig. 1). In view of the clinical findings and the small size of the sex chromatin body the extra chromosome in the D group was interpreted as a X chromosome with a deletion involving most of the short arm.

clude X isochromosomy for either the long or the short arm, deletions of the long or the short arm of the X chromosome, and mosaics with these anomalies in one of the cell lines. Based on the findings in own and published cases with such structural anomalies Ferguson—Smith and co-workers (2) have concluded that the short stature and other somatic effects of Turner's syndrome can be produced by the loss, however caused of the short arm of the X-chromosome only whereas the gonadal dysgenesis can be produced by the loss of either arm. 50 Skeletal Development as a Measure of Biological Development

E. ANDERSEN

Copenhagen County Schools

The estimation of skeletal age has become increasingly common as a measure of biological age both in transverse and longitudinal examinations.

In Denmark no systematic investigation of skeletal development has previously been made. The present study was completed in 1964 and involved a transverse examination of 1009 Copenhagen school children aged 7—18 years. The skeletal age was compared with chronological age, height and sexual development. It was of particular interest to investigate the children during adolescence because of the large range in development during this period.

Several methods of estimating skeletal age exist. In Scandinavia Elgenmark has developed a method which can be used only with children aged 0—5 years. The skeletal age of the present material was estimated according to the American atlas of Greulich and Pyle (1). The English system of Tanner and Whitehouse (2) was also applied. In this latter method the stage of development of 20 selected bones in the hand and wrist is rated on a scale of 8 (in one case 9) possible stages. Each bone *is awarded points* according to its stage of development. These points are totalled for the 20 bones and reference to a table gives the skeletal age. The later stages of carpal bone development cannot be reliably placed on the scale. Their point system is calculated in such a way that a difference of one stage in rating of a single carpal bone in older children would give rise to a difference of up to 2 years in the skeletal age estimation. A revision of the points system will probably improve the method which is, however rather time consuming to use.

Greulich and Pyle's atlas is easier and quicker to use. The present investigation has shown that this atlas can be applied to Danish children from 7—18 years of age provided that a correction of 6 months is made. Thus the average Danish boy of 12 years will have a skeletal age estimated from Greulich and Pyle's atlas of 11½ years. The American sample from which the atlas was constructed had matured under the highest socio-economic and cultural conditions and this may explain the 6-month retardation of the Danish children. The SD of the skeletal age estimation was 12 months on the present Danish material.

The skeletal age estimated by Greulich and Pyle's atlas was compared with the height and sexual development. There was a significantly higher correlation between skeletal age and height, and menarche, development

Case 2 T R. The patient was seen at the age of 20 years because of primary amenorrhoea and sexual infantilism. She had always been healthy No menstruations had occurred.

She was a rather tall girl with slightly enuchoid body proportions. Her height was 176 cm and her weight 73 kg There were no anomalies suggestive of Turner's syndrome. The breasts were undeveloped. Axillary and pubic hair were present, although somewhat sparse in the pubic region. The external genitalia and clitoris were infantile. The urinary gonadotropin excretion was 83 I U per 24 hours. An exploratory laparotomy revealed an infantile uterus and both ovaries were whitish and very small (streak gonads) Microscopical examination of biopsy specimen from the right gonad showed a fibrillious tissue without evidence of germinal epithelium or germ cells.

Cytogenetic investigations Very tiny sex chromatin like masses were present in 7 per cent of buccal mucosal nuclei Chromosomal analysis was performed on two separate occasions, both in cultured leucocytes from peripheral blood A total of 140 metaphases were examined One hundred and thirty six contained 46 chromosomes. Fifty seven cells were analysed in detail. Each metaphase contained only 15 chromosomes in the C group One chromosome which could not be paired had an acrocentric appearance and the size was about the same as an E chromosome. (Fig 2) This chromosome was tentatively identified as a X-chromosome with a deletion involving most of the long arm although the morphology resembled that of the Y-chromosome. However the evidence against this being an Y-chromosome was presence of tiny sex-chromatin like masses, absence of any testicular tissue and clinical and cytogenetic findings which were in accordance with those reported previously in cases with deleted long arm of the X-chromosome (4 5 6.)

increment measurements are presented. Sex differences are found in many of the measurements. Boys are significantly taller than girls up to 4—5 years of age and have significantly larger heads and bicondyles up to the age of 7. Regarding weight the boys are significantly heavier only up to 2 years of age. The subcutaneous tissue of girls is significantly thicker than in boys from 3 years and upwards. The subcutaneous tissue of both boys and girls is markedly increased during the first months of life but later decreases. At about five years of age the subcutaneous tissue again increases in girls but not in boys.

Diagrams for distances and increments in height, weight and head circumference are presented for use in clinical work.

52 A Longitudinal Study on Skeletal Maturation in Healthy Finnish Children up to Five Years of Age

R. L. KANTERO, R. TIISALA, L. BÄCKSTRÖM and N. HALLMAN

Children's Hospital, University of Helsinki

The Finnish longitudinal growth study project, which was started in 1953 includes a yearly determination of the skeletal age of the children at their birthdays. The present preliminary report is based on a material of 85 children who have reached the age of five years, 36 boys and 49 girls. Socio-economically they represent the middle class Helsinki population. The methods of Elgenmark and Tanner—Whitehouse have been used, the former being based on a Swedish and the latter on a British child material.

The skeletal maturation of Finnish and Swedish children was found, on the average, to correspond well. Compared with British children, Finnish girls showed no differences from British girls, whereas Finnish boys had a consistently higher skeletal age than British boys at corresponding ages.

Of genetical factors affecting skeletal maturation the influence of sex was again clearly evident already at the age of one year the overall score for the girls was significantly higher than for the boys, which means that maturation of individual bones was more advanced in girls. Another apparently genetical factor was the stature of the parents. When those children whose skeletal age at five years was one year or more ahead of their chronological age were separated, both their parents were found to have significantly higher height and weight than the corresponding averages for

of testes, pubic hair and voice changes than between chronological age and *the same characteristics* There was also a tendency to a greater correlation between skeletal age and development of breast, penis and moustache than between chronological age and the same characteristics, but no significant differences have been shown.

The skeletal development was also compared with different social conditions. The skeletal development of children where the parental occupation was manual work was significantly *more retarded than that of* children of the professional classes. No significant retardation could be shown in children from families where the assessed income was below 20 000 Danish kroner a year Whether or not the mother was employed outside the home appeared to have no effect on the skeletal development of the children But the skeletal development of children from overpopulated dwellings was retarded compared to that of children *with more adequate housing* This finding only applies to children from families where the fathers were manual workers.

51 Growth of Swedish Children up to 7 Years of Age

I ENGSTRÖM, P KARLBERG H LICHTENSTEIN and J SVENNBERG

Department of Pediatrics, Karolinska Sjukhuset, Stockholm and Children s Hospital, Gothenburg

From a longitudinal study of growth and development of children started in Stockholm in 1955 data of body growth are presented from birth to 7 years of age

The material consists of 212 children, 122 boys and 90 girls. The children have been measured at regular intervals, 7 times in the first two years and thereafter once a year on birth date This longitudinal procedure has given not only norms for different age groups but also for the rate of growth between ages.

The body parameters measured are weight height sitting height, biacromial and pelvic width bicondyle width of humerus and femur circumference of head thorax, upper arm and calf and subcutaneous tissue in four different locations.

Means for the different distance and

Thus growth hormone levels seem to be lower in infants of diabetic mothers than in normal infants, the rise in growth hormone levels after insulin-induced hypoglycemia being less marked.

This difference seems to be more marked at the age of 5—6 days than during the first 24 hrs. Even hyperglycemia induces a rise in growth hormone levels in infants of diabetic mothers, as it does in normal infants.

TABLE 1 *Data about the infants.*

	No	Birth weight	Gestation time
Normal infants	10	2.560—3.910g	38—41 weeks
Infants of diabetic mothers	5	2.370—3.800g	36—38 weeks

TABLE 2. *Growth hormone and blood glucose levels during intravenous insulin load.*

	Normal infants		Infants of diabetic mothers	
Age	5—24 hr	5—6 days	5—24 hr	5—6 days
GH-levels prior to insulin	70— 90 mμg/ml	27— 60 mμg/ml	45— 52 mμg/ml	22—37 mμg/ml
GH-levels 45 min. after insulin inject.	110—190 mμg/ml	50—110 mμg/ml	55—110 mμg/ml	32—65 mμg/ml
Blood glucose prior to insulin	38— 64 mg/%	45— 96 mg%	3— [illegible] mg%	38—35 mg%
Blood glucose 45 min. after insulin injection	5—40 mg%	22— 53 mg%	0— 15 mg%	2—20 mg%

4 IE of insulin/m² body area was given intravenously. The sample 45 min. after insulin injection in all patients showed the top values. The following samples showed rapid fall in GH-levels.

the parents of all the children The parents of children with slower than average maturation did not, however differ in their height and weight from the average levels.

Morbidity in the material was caused mainly by infections These did not have any demonstrable effect on bone maturation. Height and skeletal age were clearly correlated both boys and girls of higher than average height also had a significantly higher skeletal age than children of below average height.

It is emphasized that national, genetical environmental and individual variations in skeletal maturation must be accounted for when skeletal age is used in assessment of the influence of specific pathological factors, e.g chronic diseases on the development of children

53 Growth Hormone Levels during the First Week of Age in Normal Infants and Infants of Diabetic Mothers

O WESTPHAL

Department of Pediatrics, University Hospital, Uppsala

Growth hormone levels during intravenous glucose load have been studied by radioimmunoassay of normal newborn infants and infants of diabetic mothers.

Radioimmunoassay was carried out by minor modifications of the procedure described by Roth *et al* Blood glucose was measured with a glucose oxidase method the protein being precipitated with $Zn(OH_2)$

On 10 normal infants, delivered by Cesarean section, intravenous insulin loads with 4 IE insulin/m² body area were performed between 5—24 hrs of age and again on the same patients at the age of 5—6 days. For the study a small polyeten tube was placed in the umbilical vein. Blood samples were collected every 15 minutes until 105 minutes after the insulin injection

The same investigation was carried out on 5 infants of diabetic mothers, delivered by Cesarean section. The data on the infants are given in table 1 and the results in table 2

The infants of diabetic mothers furthermore got an intravenous injection of 0.5 g glucose/kg body weight 70 minutes after the insulin injection. 30 minutes after the glucose injection a slight second rise in growth hormone levels was registered at the age of 5—24 hrs as well as at the age of 5—6 days. This unexpected rise of hyperglycemia, earlier shown by Cornblath *et al* has been noted even in normal infants in the same age groups

appear early. Dental development measured in this way is advanced but to a much less degree than skeletal development. The results obtained are to be regarded as preliminary but may suggest that dental development is less influenced by the androgens produced by the adrenal cortex than skeletal development.

55 Circulatory and Respiratory Dimensions in Relation to Growth Differences

B. ERIKSSON

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Stockholm

The question of how a child grows with regard to height and weight has been studied by many authors. Many investigations have been made of children with differences in height — that means short and tall children — and how they differ from normal children of the same chronological age.

The development of circulatory and respiratory dimensions during growth has also been studied. We know how the heart volume changes during growth and it has been demonstrated that the best correlation is to the body surface. Lung volumes also follow the growth curve, the best correlation being to the cube of the height. The total amount of haemoglobin also changes when the child grows, the best correlation being to weight. These circulatory and respiratory dimensions also determine the functional capacity. The problem of why these circulatory and respiratory dimensions follow these parameters has been discussed. The problem of how the appearance of short and tall children is related to their circulatory and respiratory dimensions has been the aim of a pilot study. It was demonstrated in the study that some of these dimensions seemed to be abnormal in relation to the height, weight, or body surface. Thus although the vital capacity of short children seemed to be supernormal in relation to their height, their heart volume seemed to be almost normal in relation to their body surface. The total amount of haemoglobin seemed to be somewhat variable and the functional capacity seemed to be less than the normal for their age and sex. It seems to be of great interest to see whether these circulatory and respiratory dimensions follow chronological age or biological maturity. Further investigation seems to be necessary.

SESSION VI

CHAIRMAN Bo Vahlquist Uppsala

54 Dental Development in Congenital Adrenal Hyperplasia

C. G BERGSTRAND and R. FILIPSSON

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus and Tandläkarhögskolan, Stockholm

The usual way of evaluating the degree of physical maturation in growing individuals is by estimation of the skeletal development. It could perhaps be assumed that determination of the dental development would be a valuable complement especially as it is easy to perform. It has, however been found that in normal children the number of erupted permanent teeth at a certain age is not too well correlated to other indicators of physical maturation

On the other hand it has been demonstrated that in certain endocrine disorders dental development is definitely retarded and it was therefore thought of interest to study the dental development in a number of children with the adrenogenital syndrome where premature eruption of the teeth seemed likely The total material included 13 boys and 9 girls of whom 6 boys and 2 girls had been adequately treated with cortisone The rest had been inadequately treated or had received no treatment at all When the inadequately treated group was compared with a control group of normal children it was found that the dental age of the children with adrenogenital syndrome was rather evenly distributed around the normal average In a few cases it was possible to estimate the root development of the teeth radiographically this development being normally well correlated with skeletal age

Root development in these cases was advanced but to a much less degree than skeletal age A third method developed by Filipsson, was also used. The age at which minimal rate of dental eruption occurs is correlated to the degree of physical maturation In children demonstrating early maturation (e.g early menarche in girls) minimal rate of dental eruption occurs at an earlier age than in those who mature later In the children with adrenogenital syndrome minimal rate of dental eruption tends to

appear early Dental development measured in this way is advanced but to a much less degree than skeletal development. The results obtained are to be regarded as preliminary but may suggest that dental development is less influenced by the androgens produced by the adrenal cortex than skeletal development.

55 Circulatory and Respiratory Dimensions in Relation to Growth Differences

B. ERIKSSON

54 Dental Development in Congenital Adrenal Hyperplasia

C. G BERGSTRAND and R. FILIPSSON

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus and Tandläkarhögskolan, Stockholm

The usual way of evaluating the degree of physical maturation in growing individuals is by estimation of the skeletal development It could perhaps be assumed that determination of the dental development would be a valuable complement, especially as it is easy to perform It has, however been found that in normal children the number of erupted permanent teeth at a certain age is not too well correlated to other indicators of physical maturation

On the other hand it has been demonstrated that in certain endocrine disorders dental development is definitely retarded and it was therefore thought of interest to study the dental development in a number of children with the adrenogenital syndrome, where premature eruption of the teeth seemed likely The total material included 13 boys and 9 girls of whom 6 boys and 2 girls had been adequately treated with cortisone The rest had been inadequately treated or had received no treatment at all. When the inadequately treated group was compared with a control group of normal children it was found that the dental age of the children with adrenogenital syndrome was rather evenly distributed around the normal average. In a few cases it was possible to estimate the root development of the teeth radiographically this development being normally well correlated with skeletal age

Root development in these cases was advanced but to a much less degree than skeletal age A third method, developed by Filipsson was also used The age at which minimal rate of dental eruption occurs is correlated to the degree of physical maturation In children demonstrating early maturation (e g early menarche in girls) minimal rate of dental eruption occurs at an earlier age than in those who mature later In the children with adrenogenital syndrome minimal rate of dental eruption tends to

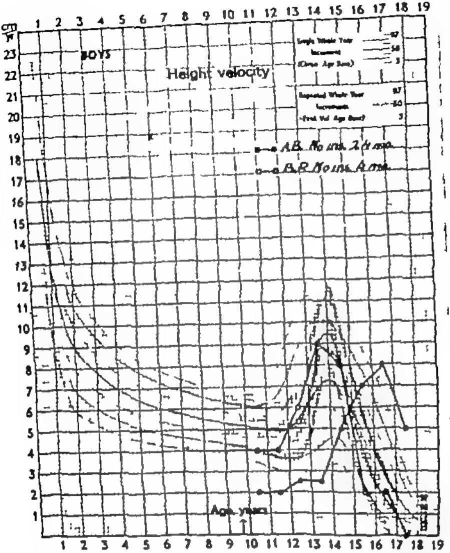

Fig. 1

During the years 1957—59 a number of diabetics who had received initial insulin treatment were given sulfonylurea drugs alone during their remission phase. They were not allowed to have glycosuria or acetonuria, or any clinical symptoms without reinstitution of insulin. Our clinical impression was that they had a somewhat reduced capacity to put on fat, in agreement with our present knowledge of lipogenesis as the most sensible indication of insulin action. The growth pattern of these children indicates that the presumed endogenous insulin release was insufficient

56 Growth Pattern in Juvenile Diabetes

G STERKY

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Stockholm

In a previous study (1) it was observed that juvenile diabetics of at least 15 years duration were somewhat shorter than normal. The reduction in height was most pronounced for men of whom 13% fell below —3 S.D

In a material of about 150 diabetic school children and non-diabetic social twins the difference in height was much more pronounced before puberty than after (2) When this material was investigated after another 5 years the same tendency was seen As previously found, diabetic girls weighed more than their non-diabetic controls after puberty but diabetic boys less in all age groups. Age at menarche was about 6 months later in diabetics.

In this follow up study those who had reached full stature were compared No diabetics fell below — 2 S D *but in the matched pairs diabetic* boys were still significantly shorter Age at onset of diabetes was without influence Skinfold thickness measured with a caliper over three sites was greater in diabetic girls and boys of all ages. When weight for a given height was expressed as S.D from the mean in a normal material the diabetics showed somewhat higher values than non-diabetics. The findings indicate a reduced muscular mass in diabetic boys and pronounced increase of body fat in diabetic girls.

All parents of subjects who had reached full stature were asked by letter to report their actual height. Parent-child correlations in height were calculated as well as midparent child data as used by Garn, Rohman (3) in other studies The figures (Table 1) for diabetics are lower in all age groups but one, indicating a disturbed growth

However at onset most diabetic boys have a slight increase in height *in comparison with normals* In the following years there is a tendency to a lowered growth velocity but a catch up growth then seems to take place.

TABLE 1

		No. of subjects	Subject's height	Father's height	Mother's height	Father child	Mother child	Mid-parent child
Boys	Diabetics	34	176.2	177.2	161 4	0.40	0 47	0.60
	Non-diabetics	21	179 4	176.5	164 2	0.50	0.68	0 72
Girls	Diabetics	28	164.9	178.4	163 9	0.48	0.36	0.50
	Non-diabetics	28	166.7	1 6.1	164.0	0.48	0 62	0 71

Mean values for parents height and parent-child correlation in diabetic and non-diabetic children, who have reached full stature.

58 Skeletal Age of Children with Congenital Heart Disease

W RYBA, G. HEDVALL, L. E. CARLGREN

Department of Radiology and Department of Cardiology Children's Hospital, Gothenburg

The skeletal age of 104 children with congenital heart disease was estimated according to the method of Tanner and Whitehouse (already described in these papers) and a new method from the Karolinska Hospital in Stockholm (Eklöf and Ringertz) The latter authors measure the length and width of some bones of the wrist, using ten parameters. Their normal material has been 1000 children, 1—15 years of age These two methods were found to give roughly equal results, and the tables presented give the values according to Tanner and Whitehouse

The patients were divided into three groups those with stenosis (33) with left-to-right shunts (51) and those with cyanotic vitia and reduced pulmonary blood flow (20) Most children with combined vitia could be put into one of these groups. A few children who had already been operated upon were included, and children with very different severity of vitium e.g small VSD without clinical significance, and major VSD with pulmonary hypertension. Children less than one year old were excluded, also those with complicating malformations or embryopathia, and those few with rare forms of vitia which could not be included in these three groups. These children were found to be slightly underweight, at least when under 7 years of age, whereas their length did not differ from the normal age groups.

As to the skeletal age no significant difference was found between these small groups, and the results are presented in a joint table. A few children can be considered to be definitely late in their skeletal age, and the group of smaller children, 1—7 years old, tends to have a lower mean value for their skeletal age than that normal for their age. The older children are normal in their distribution.

The natural selection of the patients can perhaps account for this children with severe congenital heart disease come to the clinic earlier and those with a murmur as the only manifestation come later perhaps not until school age.

The children with retarded skeletal age tend to be also small of stature for their age.

This investigation has thus shown that children with congenital heart disease are often later in their skeletal maturation than are normal children of the same age. We plan to look at a greater material of children in order perhaps, to discover something concerning the reasons for this.

for normal height velocity An example of a useful way of plotting data is given in Fig 1, where two boys who developed diabetes at the same age and have similar correlations to parents height are compared with the data of Tanner *et al* (4) Of course other factors are involved and no definite conclusions about etiology or pathogenesis can be drawn So far it has also been impossible in any of the materials to find any influence of diabetic treatment on growth

Undisturbed somatic development is however one of the primary goals in the treatment of diabetes in childhood and adolescence. In spite of definite improvements the above data may imply that this generally accepted goal has not yet been reached.

57 Physical Development of Children with Congenital Heart Disease

P SUONINEN

Children s Hospital, University of Helsinki

The physical developmental pattern of children with different forms of congenital heart disease was studied before and after cardiac surgery The height and weight of the children was correlated with the nature and severity of the heart disease, physical capacity electrocardiogram and hematological data The height and weight of normal Finnish children were used as controls. The collected data were analysed by means of a computer

The present series comprised 91 children with tetralogy of Fallot. There were 56 boys and 35 girls. Nine children received corrective surgery a shunt operation was performed in the remainder of the cases. The mean age at operation was 8.5 years

The height and weight of the boys differed more from the normal values than the corresponding values for the girls both before and after surgery The weight of boys and girls was usually more retarded than the height Children operated upon when 7—10 years old showed the best postoperative improvement. There was a correlation between the hemoglobin value and the physical capacity before and after the operation

58. Skeletal Age of Children with Congenital Heart Disease

W RYBA, G. HEDVALL, L-E. CARLGREN

Department of Radiology and Department of Cardiology Children's Hospital, Gothenburg

The skeletal age of 104 children with congenital heart disease was estimated according *to the method of* Tanner and Whitehouse (already described in these papers) and a new method from the Karolinska Hospital in *Stockholm (Eklöf and Ringertz)* The latter authors measure the length and width of some bones of the wrist, using ten parameters. Their normal material has been *1000 children*, 1—15 years of age These two methods were found to give roughly equal results, and the tables presented give the values according to Tanner and Whitehouse.

The patients were divided into three groups those with stenosis (33) with left to-right shunts (51) and those with cyanotic vitia and reduced pulmonary blood flow (20) Most children with combined vitia could be put into one of these groups. A few children who had already been operated upon were included, and children with very different severity of vitium e.g small VSD without clinical significance, and major VSD with pulmonary hypertension. Children less than one year old were excluded also those with complicating malformations or embryopathia, and *those* few with rare forms of vitia which could not be included in these three groups. These children were found to be slightly *underweight, at least when* under 7 years of age, whereas their length did not differ from the normal age groups.

As to the *skeletal age, no significant difference was found between these* small groups, and the results are presented in a joint table. A few children can be considered to be definitely *late in their skeletal age*, and the group of smaller children, 1—7 years old, tends to have a lower mean value for their skeletal age than that normal for their age. The older children are normal in their distribution.

The natural selection of the patients can perhaps account for this children with severe congenital heart disease *come to the clinic earlier* and those with a murmur as the only manifestation come later perhaps not until school age.

The children with retarded skeletal age tend to be also small of stature for their age.

This investigation has thus shown *that children with* congenital heart disease are often later in their skeletal maturation than are normal children of the same age. We plan to look at a greater material of children in order perhaps, to discover something concerning the reasons for this.

for normal height velocity An example of a useful way of plotting data is given in Fig 1 where two boys who developed diabetes at the same age and have similar correlations to parents height are compared with the data of Tanner *et al* (4) Of course other factors are involved and no definite conclusions about etiology or pathogeneus can be drawn So far it has also been impossible in any of the materials to find any influence of diabetic treatment on growth.

Undisturbed somatic development is, however one of the primary goals in the treatment of diabetes in childhood and adolescence. In spite of definite improvements the above data may imply that this generally accepted goal has not yet been reached.

Neither the etiology nor the prognosis of neonatal symptomatic hypoglycemia is sufficiently known. Many of these children, however, are small for dates. Could the abnormal carbohydrate metabolism manifest during the neonatal period be due to metabolic imprinting? Will this be reflected in further attacks of hypoglycemia or retarded somatic growth? Many

59 Influence of Physical Training on Growth? A Study on Girl Swimmers

B. ERIKSSON, C. THORÉN, I. ENGSTRÖM and P. KARLBERG

Department of Pediatrics, Karolinska Sjukhuset, Stockholm

In 1961 30 girl swimmers in hard training were examined at the age of 12—16 years. The girls showed a very high functional capacity which was strongly correlated to their large functional dimensions — heart volume, total hemoglobin and vital capacity. Intensive physical training during the period of accelerating growth might explain in several cases why these larger dimensions were obtained.

The girls were also found to be significantly taller as a group compared with untrained normal girls of the same ages. The girls were already significantly taller at the age of seven but the deviation had further increased at the time of examination. This increase in deviation was significant. One probable factor which might explain this increased height is the intensive physical training, as it is well known that physical activity stimulates production of growth hormone. To find out what happened to their dimensions and height after they were fully grown the girls were reexamined four years later. Only four out of the 30 were still active swimmers. The height of all the girls was still significantly higher than the normal, but the deviation had decreased so in relation to the standard deviation it was the same as that at the age of seven. Their functional dimensions had decreased. The total hemoglobin was now within $\pm$ 2 SD. The heart volume had also decreased but was in some cases still over two SD. The vital capacity was unchanged but the value in relation to height was around the mean value ($\pm$ 1 SD). As a result of the decrease of the functional dimensions the functional capacity measured as the maximal oxygen uptake, had also decreased and was now within normal ranges.

The results show that intense training during a period of accelerating growth leads to large functional dimensions and capacity. They decrease almost into normal ranges ($\pm$ 2 SD) after training is broken off. The study has not proved that intensive physical training is capable of stimulating the growth rate. The most probable explanation of the increased height found in the study of girl swimmers seems to be a body constitution characterized by a fast growth pattern in which an early menarche potentiates the height deviation at the age of the first investigation. This would also seem to be a prerequisite for the maintenance of intense swimming training during a period of two to three years and for the achievement of good swimming results on which principles the girls were selected for the study. The huge functional dimensions and capa

SCIENTIFIC EXHIBITIONS

intriguing questions remain to be answered

14 children from Gothenburg and 10 from Stockholm have been reexamined at the ages of 4—6 years and 8 months — 3 years respectively. Only 5 of the 24 are girls. All had a normal delivery with clinical manifestations of convulsions, apnea or cyanosis starting between 12—72 hours and persisting no longer than one week. All had a blood glucose value below 20 mg/100 ml.

At birth 14 of the 24 children fell below the 10th percentile for weight in relation to gestational age. 5 were in the 10—90 range but rather thin in relation to height. The remaining 5 including 3 of the 5 girls, were above the 90th percentile. None of the mothers have shown any signs of diabetes.

The follow up has included history of convulsions and hypoglycemia after the neonatal period, neurological evaluation electroencephalogram echoencephalogram, psychological testing, intravenous glucose tolerance test, height and weight measurements. The Gothenburg children have also been examined for ophtalmological defects, subcutaneous fat and skeletal age by the Tanner — Whitehouse method.

Among the 24 children 12 have had convulsions and 5 verified hypoglycemia. 13 show pathological electroencephalogram with paroxysmal activity and 6 abnormal neurological signs. 3 have squints and 2 of these defective vision with pale fundi. No cataracts have been noted. 10 have developmental quotients below 85 (Terman — Merill). The prognosis does not seem to be different among those with relapses of hypoglycemia, neither has any difference been detected between children with different weight at birth. However 3 of the 5 girls are heavily retarded, with developmental quotients below 50.

The somatic development is retarded (height, weight and skeletal age) among the children small at birth. This is in accordance with findings by Hepner (1963). No difference has been found in amount of subcutaneous fat.

Neonatal symptomatic hypoglycemia is not a uniform disease, though intrauterine growth often is retarded. The prognosis is grave and perhaps even worse among girls. We have not been able to find a parameter suitable for prognostic judgement in the individual case.

SCIENTIFIC EXHIBITIONS

1 Children's Nutrition Unit, a SIDA Project in the Field of Health Research

G. ALMGÅRD, K. B. BJÖRNESJÖ, Y. HOFVANDER, K. JACOBSSON
K. E. KNUTSSON, O. MELLANDER, T. MELLBIN, RUTH SELINUS
B. VAHLQUIST and G. ÅGREN

Addis Ababa, Uppsala, Gothenburg

The planning of the Children's Nutrition Unit (CNU) which is financed by the Swedish International Development Authority (SIDA) in cooperation with the Imperial Ethiopian Government, started in 1961. The work in Ethiopia began in September 1962. The aim of the project is to elucidate the frequency and character of malnutrition in Ethiopian children, to test an enrichment program with special emphasis on locally available indigenous foodstuffs, and to collaborate in the planning of nutrition programs on different levels.

For the time being seven Swedish experts, four Ethiopian counterparts, and a large staff of Ethiopian technicians are involved. There is a close cooperation between the CNU activities in Ethiopia and four Swedish university institutions, biochemical, pediatric and agricultural (in Gothenburg and Uppsala). Senior representatives of these institutions are members of a special Scientific Steering Committee.

A well-equipped base laboratory has been built in Addis Ababa and is used for biochemical and food analyses. Five field stations have been established in widely different parts of the country and it is estimated that the living conditions and the food habits in these test areas are representative of more than half of the population of Ethiopia (about 22 million). In Addis Ababa a Children's Home is connected to the Unit, where the children are living under controlled conditions with frequent medical examinations. The values obtained from this "control group" will be compared with the findings from the field stations. Different food supplementary mixtures are first tested there for acceptability.

The total number of children included in the baseline studies amounts to 2830. So far about 3600 blood samples have been taken and in addition a large number of stool and urine specimens. Careful nutrition surveys on selected groups of families

discovered and regarded as caused by prematurity and the girl was given the customary treatment. At the age of 2 /₂ years she developed severe anemia, and parenteral vitamin B_{12} treatment was initiated by the local doctor as her brother was known to have anemia responsive to parenteral vitamin B_{12} treatment.

The patient was admitted at the age of 8 years to Turku University Children Clinic. A macrocytic, megaloblastic anemia and proteinuria were diagnosed. The findings are given in detail in Table 1

It is remarkable that this patient had multiple congenital organ anomalies, namely hare lip in addition to kidney impression.

The jejunal juice used in the experiments was obtained by Miller Abbott tube from healthy serviceman, admitted to a military hospital for slight respiratory tract infection.

CASE 2 M.H. ♂

Brother of case 1 At the age of 1 / years macrocytic anemia and proteinuria were diagnosed for the first time. The patient was admitted to Turku University Children Clinic several times and treated with blood transfusions, iron, liver and folic acid. In spite of the treatment he was intermittently anemic until regular parenteral vitamin B_{12} therapy was commenced. During the summertime the patient was well without treatment, but in winter he needed monthly parenteral vitamin B_{12} injection. At the age of 15 he was admitted to the Turku University Children Clinic for thorough examination. A parenteral vitamin B_{12} injection was given two weeks before the admission so the patient was not anemic when entering the hospital, but the blood picture was macrocytic. A persistent proteinuria was diagnosed in spite of vitamin B_{12} treatment. The results are given in Table 1

The healthy person s jejunal juice used in this experiment was obtained by the same technique as in case 1 but from another military hospital patient, admitted for vegetative symptoms.

It has been suggested that a prerequisite for a normal vitamin B_{12} absorption is the existence of a hypothetic releasing factor in the small intestine. It has been claimed that this factor splits the big vitamin B_{12}-intrinsic factor complex, thus allowing the vitamin B_{12} molecule to be absorbed. It has been proposed that the disturbance in the absorption of vitamin B_{12} in this syndrome is due to the lack of this hypothetic releasing factor (Hippe 1966) The conclusions which may be drawn from the cases described here suggest rather the lack or functional disturbance of a specific receptor system in the ileal wall than the lack of releasing factor This assumption is based on the fact that a healthy volunteer s jejunal juice could not correct the defective vitamin B_{12} absorption.

have also been performed and the preparation and consumption of all dishes have been studied

In the exhibit the organization of the project the different field stations, and some preliminary results of initial cross-sectional studies are presented They include the following parameters Body height and weight in relation to age, weight in relation to height head circumference in relation to height, micro-sedimentation rate hemoglobin gammaglobulin immunoglobulins and cholesterol. To illustrate the food situation, consumption data are given from two of the field stations, where the food habits differ widely

Finally, the sero-immune patterns for a number of diseases have been investigated in order to get information on previous illnesses and present immunity situation In the exhibit the incidences of antibodies to Poliomyelitis, Measles Toxoplasma, and the AST are presented as examples of this investigation, which also includes the sero-immune patterns for Pertussis, Salmonella, Typhus fever Q fever Rickettsial pox, Schistosoma, and Syphilis.

2 Selective Malabsorption of Vitamin B_{12} with Proteinuria in Children

R. ANTTILA and H. A. SALMI

Children's Hospital and Department of Physiology University of Turku

A rare congenital familiar syndrome with clinically benign proteinuria and megaloblastic anemia due to selective malabsorption of vitamin B_{12} is known in literature as Imerslund Gräsbeck anemia

In many cases roentgenologically verifiable kidney anomalies accompany the disease. The disturbance in the absorption of vitamin B_{12} is not due to the lack of intrinsic factor but a specific inability of the small intestine to absorb vitamin B_{12}. The detailed mechanism of this defect is unknown In the literature this syndrome is called Imerslund-Gräsbeck anemia, because it was first described independently of each other in 1960 by Imerslund (1) and Gräsbeck et al (3) Altogether 23 cases of this syndrome are published in the literature The aim of this paper is to report two new cases, a brother and a sister with the clinical picture of the same syndrome.

CASE 1 P.H. ♀

The patient was born premature, birth weight 2440 grams. She was operated on for a congenital cleft lip in Helsinki University Children's Clinic and Red Cross Hospital for Plastic Surgery Slight anemia was

3 Immunoglobulin Levels in Premature Infants

T BERG S GUNNAR and O JOHANSSON

Department of Pediatrics and Blood Center University Hospital, Uppsala

Material In 47 infants with a birth-weight less than 2500 g who have been nursed at the department of pediatrics in Uppsala during the period May 1966 up to April 1967 repeated determinations of the serum concentrations of IgG IgM IgA and IgD have been made. Owing to the longer period of nursing the smallest premature infants could be followed up for longer periods than the bigger ones. In some cases determinations of the different immunoglobulin levels could be made even after the discharge from the hospital. The infants who have been subjected to exchange transfusions were subsequently excluded. Children with severe infections, for instance septicaemia, have not been included. The material has been divided into 3 groups according to the birth weight less than 1800 1800—2200 g 2201—2500 g

Method The concentrations of the different immunoglobulins have been determined by single radial immunodiffusion in agar gel according to Mancini et al. (Immuno-chemistry 2 235, 1965) This method is simple to perform, has a good precision and a fairly high sensitivity the lower limit of detection being about 1 mg/100 ml

Results

IgG While the premature infants in the two higher weight-classes do not differ from each other remarkably as regards the IgG-levels during the first weeks of life the group of children with a birth weight of under 1800 g shows a definitely lower IgG-level from the very beginning The smallest premature infants show particularly low IgG-levels, an infant with a birth weight of 1070 g had for instance an IgG-concentration of 1?0 mg* at the age of 6 weeks. The initial IgG-level seems to have a better correlation to the gestational age than to the birth-weight. Similar results have recently been presented in a preliminary report elsewhere. (Lancet I 757 1967)

IgM IgM could be demonstrated in all examined premature infants during the first 24 hours of life with an average serum concentration of 7.8 mg/100 ml. In full term babies we have previously found an average IgM-concentration of 7 7 mg/100 ml in umbilical cord serum. A strikingly rapid rise of IgM levels during the very first days of life is found in practically all infants. Although the bigger premature infants reach, on the average somewhat higher IgM levels it is obvious that in all three weight groups there exists a good ability to synthetize IgM at a very early stage. At the age of 2—3 weeks the children of the lowest weight-class show an average IgM level of 30 4 mg/100 ml. The infants in the intermediary

patient during the iontophoresis. It is also essential for the apparatus to give a sufficient strength of current even if the resistance of the skin is high. In order to obtain a satisfactory strength of current (we used 6 mA) it was found necessary to use a battery of sufficient voltage (45 V) and capacity. The patient electrodes were connected via a high resistance rheostat which gave a stable strength of current despite varying electric resistance of the patient. The apparatus that we used was constructed by Mr Agne Nilsson, engineer at the Department of Clinical Physiology.

Results. We found that 6 mA for 8 minutes in general gave satisfactory amounts of sweat. On the average we obtained 132 mg (28—312) of sweat by a single electrophoresis. There was no difference worth mentioning between different skin areas with regard to either sweat amounts or sweat electrolyte concentrations. Burns never occurred with the method used.

5 Infant Health Visitors as Collectors of Statistical Material. Five Typical Research Programs

T BIERING-SORENSEN

The Municipal Agency of Infant Health Visitors in Copenhagen

Five recent studies from the health visitors agency are demonstrated.

EMOTIONAL AND PSYCHOSOMATIC REACTION IN RELATION TO DIFFERENT ENVIRONMENTAL FACTORS

For some years the health visitors have followed one tenth of the children being supervised up to the age of 5 years, and have registered, among other things, the children's emotional stability and the presence of psychosomatic symptoms. The statistics comprise 1104 children who all have been supervised regularly during the first 3 years.

In 10 tables the influence of the housing conditions is demonstrated as well as the parents' occupation, the mother's age, the numerical position of the child in the family, weight at birth and sex, the mother's work outside the home, the mother — child contact, the principles of up-bringing employed, and whether or not the child was supervised by other persons than the mother.

As expected a distinct relation was found between the housing conditions and the children's physical stability. The psychic adaptation seemed somewhat worse when the mother was very young and in the care of only children. Peculiarly enough there seemed to be less symptoms of psychic instability at the age of 3 years among

weight-class have an average IgM concentration of 33 5 mg/100 ml and those in the highest weight-class 43 6 mg/100 ml. In a previous investigation we have found an average IgM level of 31 8 mg/100 ml in full term infants of 6 weeks Thus there does not seem to exist any essential difference between prematurely born and full term infants as regards their ability to synthesize IgM at an early age.

IgA IgA could not be demonstrated in any premature infant in the course of its first days of life The frequency of children with demonstrable IgA after that increases gradually with rising age and from the age of 4 weeks all infants have demonstrable IgA. At the age of 5—6 weeks the premature infants (all weight-groups) have an average IgA level of 6.1 mg/100 ml We have previously in full-term infants of 6 weeks found an average IgA level of 6 9 mg/100 ml

IgD In the whole material of premature infants IgD could only be demonstrated in one infant, who at an age of 3 months had an IgD concentration of 1 8 mg/100 ml.

4 Pilocarpin Iontophoresis — Practical Aspects

T BERG and L. WRANNE

Department of Pediatrics, University Hospital Uppsala

Determination of sodium and chloride in sweat seems to be the most simple and safe method to establish the diagnosis of cystic fibrosis of the pancreas. Whole body heating to provoke sweating has been found dangerous for patients with this disease. Pilocarpin iontophoresis has been widely used to induce sweating since the method was introduced by Gibson and Cooke in 1959 In our experience, however iontophoresis performed by the standard technique is often followed by small skin burns, even with scar formation There have also been difficulties in getting satisfactory quantities of sweat.

Electrodes In our experiments burns never developed under the positive electrode Many materials were used under the negative electrode. Agar gel containing electrolyte solution was found satisfactory in preventing burns 5 grammes of agar were dissolved under heating in Michaelis buffer Circular plates, 5 cm in diameter were cast and used under the negative electrode

Apparatus The electric resistance of the skin is higher at the beginning of the iontophoresis In order to construct a suitable apparatus it is necessary to take into consideration the variations of skin resistance in the

patient during the iontophoresis. It is also essential for the apparatus to give a sufficient strength of current even if the resistance of the skin is high. In order to obtain a satisfactory strength of current (we used 6 mA) it was found necessary to use a battery of sufficient voltage (45 V) and capacity. The patient electrodes were connected via a high resistance rheostat which gave a stable strength of current despite varying electric resistance of the patient. STATE OF TEETH AT THE AGE OF 3 YEARS.

In collaboration with Dental College of Copenhagen" children supervised to the age of 3 years have been examined with regard to the conditions of the teeth, among other things to investigate a possible correlation with the habits of eating

As expected an increase of the frequency of caries was found in cases where the children had oversweetened food, or where the mother was apt to give the children sweets between meals.

SUDDEN UNEXPECTED DEATH OF BABIES.

An examination of the health visitors case records for the last years showed 58 babies who had died during the 2nd—1"th month of life — and where the post mortem diagnosis from the Medico-legal institute was

"SUDDEN UNEXPECTED DEATH

In the material there are 19 girls and 39 boys. The greater number of boys is rather conspicuous, if one excludes the 13 girls and the 12 boys *where post mortem examination* showed signs or suspicion of an acute infectious disease.

Of the remaining 33 children 27 were boys and 6 were girls a find which to a great extent supports the assumption that a hormonal factor contributes to the pathogenesis.

Furthermore it is seen that none of the children have had pure breast feeding at the time of death, and also that the period of suckling on a whole has been considerably shorter than for children generally

6 Age Distribution and Life Span of Foetal Red Blood Cells Present at Birth

L.-E. BRATTEBY and B. WADMAN

Department of Paediatrics and Medicine and the Swedish Medical Research Council Unit for Experimental Haematology University Hospital, Uppsala

Evaluation of red blood cell life span necessitates a knowledge of the age distribution of the cells. In the normal steady state all age groups of red blood cells are present in equal numbers When the steady state is not present information about the age distribution can be obtained from data of production and destruction of red blood cells. Such data regarding the erythrocytes of the human foetus are not yet available. However the

children of a low birthweight than among those of a normal weight There was no sign of difference between boys and girls

Regarding the mother's employment outside the home there was a distinct tendency towards fewer psychic problems in children of mothers working part time outside the home than for children of mothers staying at home A good mother—child-contact proved to have a beneficial influence while on the other hand a rigorous up-bringing gives a high degree of psychic instability

THE DAILY INCREASE OF WEIGHT OF BABIES DURING THE FIRST 6 MONTHS OF LIFE

As errors have been found in the tables at present used for the babies growth new tables have been worked out, the material exclusively comprising children who have been supervised during the first six months of life The children have been weighed on the visiting nurses verified scales at the age of 1 2 3-4 and 6 months and complete statistical correction has been made in all cases when the day of weighing deviated from the 30 days interval

The table mentioned below which with a good approximation indicates the values for healthy breast fed children as well as the necessary corrections for artificially fed children, may be recommended for use in practice as a mnemonic guide

MORTALITY AND CAUSE OF DEATH during 2nd—12th month of life

The statistical survey comprises all children under the supervision of health visitors in the Municipality of Copenhagen during the years 1940—1962 In all, the material comprises 231 400 children in wedlock and 26 800 born out of wedlock, of which respectively 1722 and 344 died during the 2nd—12th month of life.

Through the whole period the mortality remained almost twice as high among children born to unmarried mothers, although the total mortality fell from about 1½ to 1/3% This high mortality was mainly due to various infectious diseases, whereas there was no real difference of mortality because of congenital malformations

	Average increase of weight for breast-fed children			Correction for children artificially nourished	
	grams per day	grams per week	grams per month	percentage deviation	increase of weight per day

7 A Cornelia de Lange's Syndrome I — Like Case with Inherited Chromosome Aberration

K.-A. BROHOLM, O. EEG-OLOFSSON and B. HALL

Department of Pediatrics, University of Gothenburg, and Department of Genetics, University of Lund

Cornelia de Lange's syndrome I is essentially characterized by low birth weight in spite of delivery at term, retarded growth, psycho-motor retardation, microbrachycephaly bushy eyebrows with synophrys, long curved eye-lashes, short upturned nose with flat bridge, elongated philtrum, carp mouth, low set ears, dysplastic hands with proximally placed thumbs and dysplastic feet with syndactyly of second and third toes.

The etiology of the syndrome is obscure A chromosome aberration

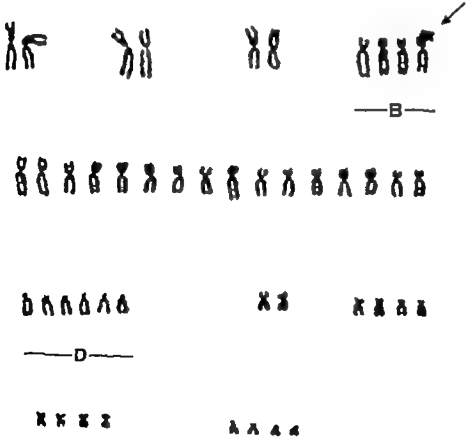

Fig 1 Proband B/D translocation + normal D chromosomes (partial D trisomy).

increase of circulating red cell volume during the last months of foetal life (Fig 1) is an expression of the minimum production i e. the increase of red cell volume equals the production if there is no destruction This estimated minimum production will give rise to a population of red cells, in the newborn infant, with a disproportionate number of young cells (Fig 2) In fact the age distribution is probably even more asymmetrical as the calculated production of red blood cells was underestimated Assuming a mean potential life span of 120 days for cord red blood cells, the uneven age distribution will result in a convex survival curve as shown by a broken line in Fig 3 Cord red blood cells from nine healthy full term infants were labelled *in vitro* with $DF^{32}P$ and transfused into nine haematologically normal adult recipients. The results of these studies are given in Fig 3 The mean life span of these cord red blood cells is apparently considerably less than 120 days. Quantitative calculations of life span distribution are now in progress

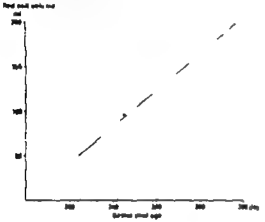

Fig 1 Circulating red cell volume measured by ^{51}Cr technique in newborn infants of different gestational age.

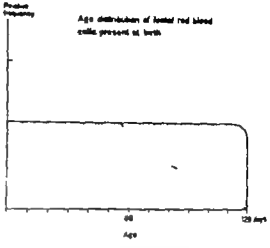

Fig 2 Age distribution of red blood cells in the normal adult (continuous line) — and in the newborn infant (broken line)

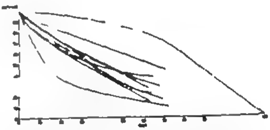

Fig 3 Survival of $DF^{32}P$ labelled cord red blood cells transfused into adult recipients. The broken line shows the expected survival curve assuming a mean potential life span of 120 days.

examined. The proband has only three normal B group chromosomes. Instead of the missing B group chromosome, a chromosome similar in size and morphology to a chromosome no. 3 was found. The D group chromosomes looked normal (Fig 1) The mother and sisters of the proband showed the same picture except for a D group chromosome the long arm of which looked shorter than normal (Fig. 2) The father and the parents and a sister of the mother had normal karyotypes. Hence it is evident that the mother and sisters of the proband have a balanced translocation, a B/D translocation The karyotype of the proband with the normal chromosomes in the D group should thus be regarded as a partial D trisomy

The dermatoglyphs of the proband showed a strikingly lower total ridge count and strikingly higher maximal *atd* angle than those of all her relatives. This fits rather well with the findings in cases of de Lange syndrome reported by Smith (2)

Much argues for this being really a case of Cornelia de Lange's syndrome I but due to the atypical clinical findings mentioned above, we do not consider that a definite diagnosis can be made.

CASE REPORT

The patient presented was a boy the first child of healthy unrelated parents with no known diseases in the family Pregnancy labour delivery and neonatal period were normal. Feeding difficulties and slow development were noted early At the age of 3—4 months the child lost the ability to lift his head in the prone position. He showed no interest in his surroundings and became increasingly irritable. Short tonic fits started. Fever periods occurred without signs of infection.

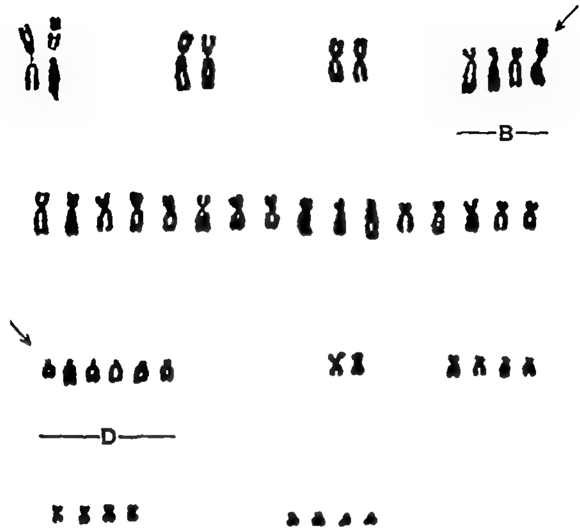

Fig 2. Mother and sisters Balanced karyotype with B/D translocation and deleted II chromosome.

has been discovered in 16 of the approximately 100 cases described in the literature The findings have been described as fragmentation deletion pericentric inversion and transloca tion In spite of normal chromosomes in 20 cases, McArthur and Edwards (1) consider the chromosome aber ration etiology most likely

An eight year-old girl with congeni tal heart disease epilepsy and mental retardation presented an appearance typical of Cornelia de Lange s syn drome I except for normal birth weight normal growth verified by normal ossification age, normally placed thumbs and no carp mouth Detailed clinical and laboratory in vestigations were performed The ap- pearance of the parents and two sis- ters of the girl showed some minor peculiarities. One brother died at the age of two days from multiple mal formations

Chromosomes of the proband and her relatives were studied in blood The modal number of chromosomes was 46 in cultures from all persons

9 Renal Diabetes Insipidus

K. B. GAVIN

Department of Pediatrics, Sentralsykehuset, Trondheim

Renal diabetes insipidus is a rare hereditary disease characterized by impaired absorption of water in the distal renal tubules, and absence of an increase in renal concentrating ability in response to vasopressin. In the following two affected siblings are presented.

Case 1

Boy S. L., aged 15 months. No information about hereditary disorders in the family parents non consanguineous. The pregnancy delivery and neonatal period uncomplicated. Birth weight 2210 g The child had "always vomited and was frequently constipated Since 6 months of age there were episodes of intermittent fever and profuse sweating. From the age of 7—8 months he displayed signs of motor and mental retardation At admission the boy was hypotonic The skin had a peculiar pasty" consistency The urine was very dilute, the specific gravity varying between 1 002 and 1 015 Serum sodium ranged from 146 to 168 mEq/l (average value 156 mEq/l) Serum chloride level varied between 102 and 132 mEq/l (in average 124 mEq/l) Serum cholesterol on two determinations showed 287 and 350 mg per 100 ml. 200 mU of pitressin given intravenously in the course of one hour failed to produce a urine more concentrated than serum

The patient was given diet low in electrolytes and one tried to give substantial amounts of fluid. This was not always successful, partly because of the patient s refusal to drink, partly because of vomiting A therapeutical trial with Hydrochlorothiazid (Fig 1) significantly lowered the serum sodium and chloride, but the effect was of relatively short duration (some weeks)

The boy has been controlled regularly in the clinic. He is extremely retarded. At 3 years of age he is still unable to walk alone, and he speaks only a few words.

Case 2

Boy J L., aged 5 months. The pregnancy delivery and neonatal period uncomplicated. Birth weight 3600 g. Since 2 months of age episodes of fever At admission his appearance was much like his brother s, and the same "pasty" consistency of the skin was noticed. The specific gravity of the urine varied between 1 004 and 1 010 Serum sodium was 158 mEq/l serum chloride 117—127 mEq/l Serum cholesterol 272 mg per 100 ml The pitressin infusion test was similar to that of his brother

When examined at the age of 7 months he showed no interest in his surroundings and reacted neither to light nor to sound and only slightly to tactile stimulation Pupils reacted sluggishly to light eyegrounds appeared normal The boy was lying in a froglike position he had severe muscular hypotonia and moved very little Reflexes were normal for age Spinal fluid was normal Two earlier electroencephalograms were normal, a third, recorded 3 weeks before his death showed paroxysmal spike activity

His condition deteriorated he became febrile and died at the age of 8 months.

Autopsy findings

On macroscopic examination of the central nervous system abnormalities were seen mainly in the brain stem. A T shaped brownish red lesion was found in the lower part of the mesencephalon and the upper part of the pons under the aqueduct and in the bottom of the fourth ventricle it extended a few mm from the midline on both sides. The posterior columns of the spinal cord were slightly thin and pale particularly in the thoracic region

Histological examination revealed severe demyelinization which besides the lesion seen macroscopically included also the brachium conjunctivum at its decussation and the longitudinal medial fascicle. The findings had the character of astroglial scar tissue with sudanophilic macrophages and marked proliferation of capillary vessels. In addition the superior cerebellar peduncles and the posterior columns of the cervical and thoracic spinal cord were partly demyelinated with only slight gliosis and no capillary proliferation findings characteristic of secondary tract degeneration. Mild gliosis was noted in the optic nerves.

Other autopsy findings were bronchitis, bronchopneumonia, focal pulmonary atelectasis a septic spleen and signs of terminal circularatory failure

Discussion

The clinical picture and the histopathological abnormalities are in agreement with findings previously reported under headings such as chronic Wernicke-encephalopathy or subacute necrotizing encephalomyelopathy About 30 cases are now on record The first case was reported by Leigh in 1951 (2) and the present knowledge was summarized by Lakke *et al* 1967 (1)

A metabolic disorder probably with recessive autosomal inheritance, is assumed to lie behind the condition. Impaired thiamine metabolism and increased production of lactic acid are the two explanations most discussed although neither has been proven

10 Impedance Pneumography in Newborn Infants

M. DAHL and L. VALIMAKI

Children's Hospital and Cardiorespiratory Research Unit, University of Turku

In 52 healthy fullterm newborns (25 girls and 27 boys) a simultaneous recording of impedance pneumogram (IPG) and EKG was made The apparatus consisted of Impedance Pneumograph preamplifier (E&M) T M C-unit (E&M) and Mingograph 24 (Elema) The ages of the newborns varied from 1 hour to 10 days. From the IPG it was possible to count the frequency of the regular respiration and the change in the impedance (ΔZ) caused by respiration. ΔZ is proportionate to the depth of respiration. The pulse frequency was seen from the EKG The newborns were examined in the supine, prone, right and left lateral and upright positions The IPG was recorded in the anteroposterior (AP Lead) and lateral ('C6-O6R Lead) directions.

It was shown that

— ΔZ (depth of respiration) was maximal both in boys and girls in the prone position in the anteroposterior recordings. Also in the lateral recordings the boys had the highest values in the prone position whereas the girls had the same maximal depth both when lying on the left side and in the prone position.

— correspondingly the frequency of respiration was, on an average, lowest in the prone position, both in boys and girls.

— the regular respiration was often interrupted by short pauses and therefore the frequency was in reality lower than indicated by the frequency of the regular respiration.

— a Cheyne-Stokes-like rhythm was found in 29 newborns.

— the IPG recording was disturbed by cardiogenic changes of impedance in some cases.

Besides this series a simultaneous x ray cinematographic film of the chest and an IPG recording was made on a premature boy (birth weight 2350 gr)

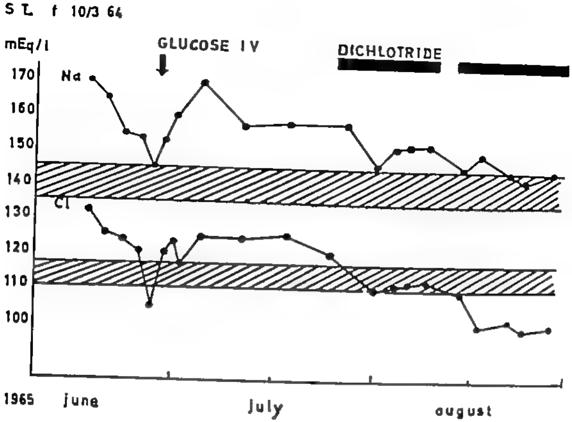

Fig 1 Renal diabetes insipidus. Treatment with Hydrochlorothiazid.

This boy was treated according to the same principles as his brother The results of the therapeutic regime seem to be much more satisfactory than in the first case At two years of age he walked alone and said many words.

12 Acute, Lethal Poisoning after Ingestion of Metallic Lead

N. FORSBY B. FRISTEDT and B. KJELLMAN

Department of Occupational Medicine, Department of Pathology Department of Pediatrics, University Hospital, Lund

This previously healthy 2 year-old girl was admitted to hospital with vomiting of 10 days duration. She had normal stools, normal temperature and no catarrhal symptoms.

She was pale and lethargic The muscle tone was slightly increased and her neck stiff. She had spontaneous vertical nystagmus and normal optic disks. Haemoglobin was 9 4 gm/100 ml. Stippling of the red cells was noted (299/10 000 counted cells) White cells were 13600/cmm with a normal distribution. Serum electrolytes and glucose were normal There was no albuminuria and urinary sediment was normal. Analyses of cerebrospinal fluid disclosed 0 red cells, 7 white cells 73 mg/100 ml protein and 83 mg/100 ml glucose. EEG showed a slow background activity but no focal abnormalities Inquiries about medicines and poisons were negative The girl died 24 hours after admission.

At postmortem examination a lead button with a diameter of 22 mm was found lying free in the stomach The brain showed oedema with signs of increased intracranial pressure and herniation. There were multiple subependymal petechial haemorrhages in the third ventricle Microscopic examination revealed tiny cortical microinfarcts with disappearance of some neurons and glial proliferation. The parenchymatous organs showed toxic changes. No "dead line" was found in the gingivae. X ray of the femur revealed no deposits in the epiphyses. The following tissue concentrations of lead were found brain 0 69 mg/100 g, liver 5 4 mg/100 g and kidney 3 0 mg/100 g In relation to corresponding figures in the literature these values are extremely high

The button was of a type used as *curtain* weights in the girl's home and still available in the shops. Children can easily swallow them and if arrested in the gastrointestinal canal they can cause severe lead poisoning

11 Methodological Considerations Concerning Blood Glucose Determination in Newborn Infants

J EK

Department of Pediatrics, Ullevål Hospital, University of Oslo

Many methods for the determination of blood glucose concentration are found quite reliable in children and adults. In the neonatal period however special conditions prevail Very low blood glucose concentrations are concerned, and to evaluate the hypoglycemia problem it is necessary to choose methods of glucose determination which are reliable at these low levels

A comparative investigation was performed in which four commonly applied routine methods were used the method of Hagedorn Jensen, based on the reduction power of glucose two modifications of the glucose-oxydase principle and a method based on the colour formation between glucose and orto-toluidin (Hultman) Dextrostix was investigated simultaneously as a screening test

The material consisted of 50 full term, newborn infants and 11 infants of low birth weight. The fasting blood glucose concentration (capillary blood) was determined simultaneously by all methods on the second or third day of life (mean age 46 hrs) Galactose was estimated in all infants to test the reliability of the orto-toluidine method. Only traces of this sugar were demonstrated.

The normal ranges and mean values were estimated The mean values varied from 34—56 mg glucose/100 ml according to the method employed. The method of Hagedorn Jensen (1) yields too high values, because other reducing substances than glucose are present. The glucose-oxydase method with protein precipitation by means of buffered perchloric acid (5) yields too low values, mainly because of the interference of glutathione. — The orto-toluidine method (3 4) and the glucose-oxydase method with precipitation of the proteins by means of NaOH $ZnSO_4$ (2) both yield results which are close to or equivalent to the true glucose concentration Only these two methods are satisfactory with regard to the low blood glucose concentrations from a pediatric point of view

Dextrostix is not reliable as a screening test in the very low blood glucose concentrations in newborn infants.

13 Favorable Response of Chronic Candidas to Amphotericin B

S. HOYER and P J MOE

Department of Pediatrics, University of Bergen

A girl aged 9 years had had cutaneous, oral and gastrointestinal lesions since the age of 1 year Most of the nails were also involved (Figure 1) The sputum and stools contained candida albicans No endocrine disturbances were noted

Conventional fungicidal therapy was tried without any improvement. Intravenous amphotericin B resulted in healing of the lesions (Figure 2) Mild relapses have been controlled with intravenous amphotericin B, and lately amphotericin B ointment.

Fig. 1 Hands and feet of a 9-year-old girl with chronic moniliasis before institution of amphotericin B treatment.

14 Death from Asthma in Children and Adolescents in Finland in 1952—65

A. KOIVIKKO and T. PELTONEN

Children Hospital, University of Turku

Death from asthma is not rare, in spite of the improved therapy. Richards and Patrick in Los Angeles observed in 1965 that death from asthma and admissions to hospital had increased during the previous 20 years.

Data for this study was collected from the archives of the Central Office of Statistics in Finland. All the cases in which asthma was diagnosed were registered. When patients had been in hospital the hospital records were also studied. Cases in which asthma was probably not responsible for the death were excluded. It was not possible to decide if respiratory infections were present, and to what degree. Therefore the present material

comprises all those cases in which in fection seemed to play an important role.

Results

From 1952 to 1961 deaths from asth ma seem to have decreased consider ably (from 6 to 2 cases per year) This may be explained by a decrease in mortality in the age group from 0 to 3 years. In 1961 the mortality rate seems to be at its lowest, and then it increases again (from 2 to 6 cases per year) This latter increase occurs only in the age groups from 3 to 20 years. The decrease in the youngest group is best explained by the improved therapy in respiratory infections, be cause at the same time there also seems to have been a clear decrease in mortality resulting from respiratory infections in this age group It seems impossible to explain completely why the death rate should have increased again in the older groups When the patient reports were studied, we could observe that many of the older pa tients had already suffered from severe asthma for many years. They had often received ACTH or corticoster oids over long periods of time In some cases we considered the possibili ty of an overdose of bronchodilating agents or sympathomimetics. In too many cases patients were brought to the hospital in a moribund state

To get some idea about the develop- ment of morbidity in asthma, our own asthma cases were studied We observed that from 1952 to 1965 there was a large increase of asthma admissions (from 25 to about 50 cases per year) Also there were many more new cases of asthma in 1965 than in 1952 (10 vs 30 cases)

15 Gastric Secretion in Early Childhood

P A. KRASILNIKOFF P RODBRO and P M. CHRISTIANSEN

Department of Pediatrics and Department of Medicine, Glostrup Hospital and Department of Surgery Bispebjerg Hospital, Copenhagen

The gastric secretion of acid and in trinsic factor was studied after stimu lation with 40 microgram histamine diphosphate per Kg body weight in 18 children (aged between 9 and 30 months) without gastrointestinal dis- orders.

As in adults the secretory patterns after stimulation showed a sustained response for acid a wash-out response for intrinsic factor The maximal con centrations of both components were about half of those found in healthy adults.

The stimulated hourly output of acid varied between 0 27 and 3 73 mEq and was related to age body weight and body surface area. The

stimulated hourly output of intrinsic factor varied between 1050 and 3965 units and was also related to age, body-weight, and body surface area.

Acid and intrinsic factor are both products of the parietal cell. The present results indicate a dissociation in the parietal cell function in the first years of life, as the secretion of intrinsic factor is more mature than the secretion of acid.

16 Autoimmunity in Ulcerative Colitis

R. LAGERCRANTZ, S. HAMMARSTRÖM and P. PERLMANN

Pediatric Department, Karolinska Sjukhuset and Wenner-Grens Institute for Exp. Biol., Stockholm

In sera from patients with ulcerative colitis an increased incidence of elevated autoantibody titers against colon antigen(s) has been demonstrated. These titer values are not elevated in patients with bacillary or amoebic dysentery, Salmonellosis or ulcerous cancer coli. The autoantibody titers in ulcerative colitis do not correlate with clinical factors such as extent of colon lesions, duration or severity of disease or presence of extracolonic symptoms. Pancoloproctemy does not seem to influence the titer levels. Lymphocytes from patients with ulcerative colitis have cytotoxic effects on foetal human colonic mucosa cells grown in vitro, sera have not. The colon antigen is a mucopolysaccharide related to but immunologically distinct from blood group substance A and H. The autoantibodies are usually found in 19S — immunoglobulin and to a lesser extent in 7S.

The colon antigen from man, rabbits and rats cross-react. Immunization of rats and rabbits with homologous and heterologous colon antigen in Freund's complete adjuvans provoked autoantibodies against colon. The colon antigen cross-reacts with a bacterial antigen from E. coli 0 14. The incidence of elevated autoantibody titers against colon is higher among relatives of patients with ulcerative colitis than in the general population.

Autoimmunity in ulcerative colitis might possibly be provoked by immunization (infection) with a bacterial strain cross-reacting with colon antigen(s) which in predisposed individuals breaks the natural tolerance. This might possibly be of importance in the pathogenesis of the disease.

17 Physical Training for Babies

P J NORDENFELT

Stockholm

Three movements are recommended, each to be practised four or five times every day at two or three of the daily nursing hours. Training may be commenced when the child is two or three weeks old. At this age the child has a high muscular tonus (strength) and can be lifted quite easily by his arms or legs. If training is started later, more care must be exercised in the beginning. The movements should always be performed gently and slowly, while watching the child. The child must take active part in the exercises.

The movements (directions for use)

1) put hands around the child's body supporting his chest with the palms, lift the child into the air
2) put hands around the forearms of the child, thumbs in the firm grip of the child's hands (resting between his finger and thumb), lift the child into the air
3) take a firm grip around the child's ankles, lift him into the air, his head down

This last exercise should be presented with special care so as not to frighten mothers and nurses. The child usually enjoys this exercise best of all.

This training program gives the child not only a well-developed musculature but also an increased confidence, a better ability to get on successfully in unusual situations, and a greater inclination for moving than other children. Young parents usually learn very soon to handle their child with confidence and sureness (without fear or insecurity). The child gains, in addition, an increased feeling of security through the close communication with his parents at training intervals.

For twenty years or so this training program has been recommended and demonstrated to many mothers at my infant care centre in Stockholm and privately. A great number of parents have continued the daily program every day over a long period.

No disadvantages whatsoever have been observed; the parents have been happy and satisfied, and the children showed, quite obviously, greater activity and mobility by the end of their first year than did children who had had no training program.

However encouraging, it is not these results that have led to physical training for babies being presented here now, but the observations made during the last three years at a children's home. This home — Lillgården, Upplands Bro — accommodates 16 children, most of them newborn, transferred directly from the maternity hospital. According to a unanimous report by the staff responsible, this form of physical training has, in a conspicuous way, improved the development of the children.

My colleagues are therefore recommended to introduce the system in all departments, with healthy children.

Physical training of this kind has been practised in several countries in Finland, for instance, it has already been recommended for a considerable period at the infant care centres in Copenhagen and Oslo it was practised for some years during the forties Professor A. Tour and others in Leningrad have for many decades now been advocating systematic physical training for babies.

18 Sound Spectrography in Pediatric Diagnosis

J LIND O WASZ-HÖCKERT G ROSBERG K. THEORELL
E. VALLANE, T PARTANEN and V VUORENKOSKI

The Wenner-Gren Research Laboratory Norrtull Hospital, Stockholm and Department of Pediatrics, University of Oulu

Part I

SPECTROGRAPHIC IDENTIFICATION

44 spontaneous cry signals recorded before the meal from 8 infants with the chromosomal syndrome Maladie du Cri du Chat and 38 pain cry signals obtained after a single pain stimulus (pinching) from 20 infants with Down syndrome and from 8 with Kernikterus and 10 with hyperbilirubinemia have been analyzed with sound spectrographs.[1] It has been demonstrated that these three groups have cries which are specific and different from the normal material

[1] Sona-Graph 661 A, made by Kay Electric Co., N J and Voiceprint, made by Voiceprint Laboratories, Inc Somerville, N J

Part II

AUDITIVE IDENTIFICATION COMPARED WITH SOUND SPECTROGRAPHY

90 pediatricians, general practitioners and medical students were tested as to their ability to recognize the cry response to painful stimulus (pinching) of ten newborns and young infants with asphyxia or brain damage from randomized series of ten normal pain cries. The results indicate that the average number of correct answers was 15 4 out of 20 cry samples. The best identification (90—97 %) of pathological cases was made in 3 perinatally asphyctic, brain damaged cases and in 2 cases with hyperexcitability syndrome. The spectrograms of these cries show also the most evident

difference from cries of normal infants. The cases of hyperbilirubinemia, chromosomal aberration and hydrocephalus have also been well identified (81—89%). Only one of the pathological cries was poorly identified (47% diagnosis meningitis E. coli). The acoustical features of the best and poorest identified pathological and normal cries are shown and compared with normal material.

19 The Smaller of Twins and Hypoglycemia

S. OSEID and O. AAGENÆS

Pediatric Research Institute, University of Oslo, Rikshospitalet

Spontaneous delivery 5 weeks before term because of severe toxemia. Identical twins with birth weights of 2170 g and 1500 g. Both were placed in an incubator for 6 weeks. No convulsive episodes occurred and there was no clinical suspicion of hypoglycemia.

The bigger twin has developed normally but suffers periodically from headaches. An abnormal EEG was found in 1966; there has been no improvement on Fenemal treatment.

The smaller twin has occasionally complained of abdominal pain. 4 years old he was referred to hospital with generalized convulsions and hypoglycemia. A similar attack occurred 6 months later.

There has been a tendency to hypoglycemic episodes during the night and early morning; these have been relieved by food intake.

There are no abnormal findings on physical examination, EEG is normal.

The smaller twin develops hypoglycemia on fasting over 14—16 hours. There is no increase in glucose levels following glucagon administration after a 24 hours fast, while there is a normal response following fasting over night. There is an exaggerated response to insulin with fall in plasma glucose level to 18 mg/100 ml following insulin 0.1 i.u./kg intravenously. The HGH response is normal; there is also an increased excretion of catecholamines following insulin administration. The leucine tolerance test is normal.

All tolerance tests are normal in the bigger twin.

There is no difference in intellectual development, both twins being normal.

The tendency to hypoglycemia in the smaller twin is probably related to intrauterine malnutrition in a twin small for date.

20 Perinatal Mortality in North Finland Correlated to Social and Economic Factors

A Community Study

P RANTAKALLIO

Department of Pediatrics, University of Oulu

This is a community study covering some 12,000 childbirths in North Finland in 1966. The area involved covers about 160 000 sq.km, extending 390 km north and 350 km south of the Arctic Circle The total population is about 660 000 The study is prospective information on participants was collected by questionnaire prior to the delivery and information on the child's fate up to the age of 28 days was obtained in follow-up examinations. Information is available on 97 per cent of the deliveries in this area during 1966 All cases in which the child's birth weight was not less than 600 g were classified as deliveries.

According to the preliminary data available the perinatal mortality in the material is 2 6 per cent, including 1 4 per cent stillbirths. 52 per cent of the perinatal mortality in single births consists of infants with birth weights under 2500 g The perinatal mortality of these infants is 33 per cent. The total frequency of infants with birthweights under 2500 g is 4 1 per cent.

For treatment of the data, separate groups were formed of children who died in the perinatal period, of all twins, and of children with birth weights under 2500 g. 1000 controls were obtained by random sampling from the remainder approximately 11 000 infants, using a computer

The attached table shows perinatal mortality in the different groups in relation to the father's occupation.

Father social class	Control group %	Perinatal deaths all %	Perinatal deaths birth weight under 2500 g %
I	3.3	3.5	3.1
II	13 4	14.3	15 9
III	34.3	31.2	30.5
IV	17 7	20.5	20 1
Farmer area of land under plough 8 hectares or mor	8.8	6.2	5.5
Farmer area of land under plough less than 8 hectares	14.9	14.9	14.6
Unknown	3.6	7 4	10.3
Total	100.0	100.0	100.0

A detailed analysis will be carried out concerning the influence of the different factors on the child's birth weight and perinatal mortality in the present material. The study of the surviving children will also be continued: their growth and development will be followed up and the high risk groups analysed.

21 Follow up Study of 18 Infants with History of Coxsackie B-5 Virus Meningitis during Neonatal Period

P. RANTAKALLIO, A. L. SAUKKONEN, U. KRAUSE
and O. WASZ-HÖCKERT

Department of Pediatrics and Department of Ophthalmology, University of Oulu

The series consists of 18 full term infants who had had Coxsackie B-5 meningitis in their neonatal period in July—September 1966. Fig. 1 gives their dates of birth, ages at onset and periods of hospitalization. Seventeen of the children acquired the infection at Oulu Municipal Maternity Hospi

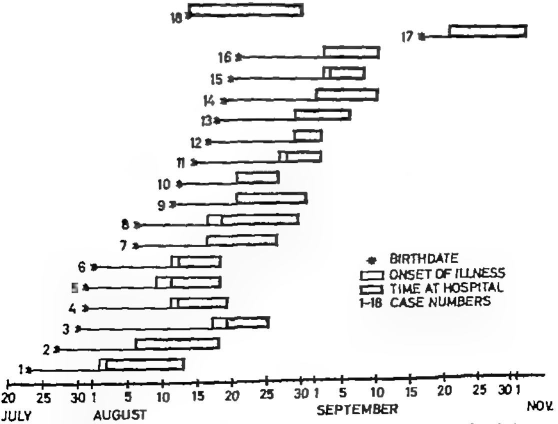

Fig. 1. Children's birthdates, dates of onset of illness, and time spent at hospital.

tal and one (Case 18) at Oulo University Obstetric Clinic. The virological and serological diagnoses were made at the Turku University Institute of Virology Turku, and the State Serum Institute, Helsinki.[1]

The cells in the cerebrospinal fluid of all the cases except one exceeded 100 per cu mm, and in five cases 1 000 per cu mm. Other symptoms common to all cases were fever hyperirritability and anorexia. The symptoms began on approximately the 7th day of life, except in Case 18 where infection had been acquired in utero this infant had been delivered by Caesarean section since the mother had high fever Myocarditis was suspected in the child immediately on birth, and verified later

No instance of subdural effusion was noted in the series.

At follow up examination at the age of 6 months the neurological status and development of all the children was found to be normal. Their weight, height and circumference of head were within the normal limits. Skull and thorax x ray were normal, except for Case 18, the child with myocarditis, whose heart was dilated. The ophthalmologic findings are shown in Fig. 2. Suspected positive findings numbered 7 of the 18, although the causal connection with meningitis was definite only in the suspected optic atrophy The findings will be analysed in greater detail in connection with the follow-up examination at one year

[1] By Kaisa Lapinleimu, Reino Mäntyjärvi and Paula Rantakallio the results will be published separately

Case Number	Findings	Case Number	Findings	Case Number	Findings

is replaced. The prosthesis also makes the feeding easier closing part of the palatal defect. Careful control and adjustment of the prosthesis prevent the formation of pressure sores.

As soon as the orthodontist is satisfied as to the alignment of the dental arch, the child is transferred to the plastic surgery department for operation. The hard palate, the floor of the nostril and the lip are then closed. In the afternoon the child is re-admitted to the pediatric department. The bilateral cases are operated upon in two sessions. Six days after the operation the child is discharged to its home.

At the age of two years, the patient is admitted to the Plastic Surgery Department for closure of the soft palate. In the meantime the child has been under the surveillance of the orthodontist, but no major orthodontic treatment is given until the appearance of permanent teeth.

Children with cleft palate only — group III — are also operated upon at the age of two years, and are of minor interest as far as the orthodontist is concerned.

It is a well known fact that some children with cleft palate are more prone to oto-laryngological disorders than other children. The oto-laryngologist is therefore an important member of the team.

As the child grows older and starts talking the speech therapist comes into the picture to assess possible speech defects and give advice. Speech therapy is started when considered necessary.

At the age of five it must be decided whether the child will need an additional operation to achieve an adequate oro-nasal sphincter mechanism. If this is considered indicated, the child is then admitted for operation. At the same operation minor labial corrections may be carried out.

In the following years the child should be regularly studied and examined by the team. The orthodontic member is usually the most active in this period, guiding the erupting teeth into normal position.

Final correction of the lip and the nose, including submucous resection of the nasal septum, is delayed until the age of 14—15 depending on the physical development of the child.

A retention bridge to maintain the dental arch is not permanently constructed until the age of 18. Then — and only then — can the result of the treatment be finally assessed.

22 Teamwork in the Treatment of Cleft Lips and Palates

H. SCHJELDERUP and S. KVINNSLAND

Department of Plastic and Reconstructive Surgery, Department of Pediatrics, Haukeland sykehus and Orthodontic Department, The Odontologic Institute, University of Bergen

The treatment of children with cleft lips and/or cleft palate is both difficult and time consuming. It covers so many fields of medicine that multilateral teamwork is necessary.

Members of the team being developed in Bergen are the following: plastic surgeon, pediatrician, orthodontist, otolaryngologist, speech therapist and child psychiatrist. It is considered feasible that the plastic surgeon should serve as the coordinating member of the team.

Classification

As demonstrated in the exhibition the following classification is used.

Group I

In these cases only unilateral or bilateral clefts of the lip are present. The alveolar process and the palate are unaffected, with certain exceptions (see group III).

Group II

In these cases the cleft extends from the lip right through the alveolar ridges and the hard and soft palate. There may be an unilateral or bilateral cleft, the latter representing the most difficult problem both surgically and orthodontically.

Group III

In the majority of cases a cleft affects the palate only. There are varying degrees from bifid uvula to a cleft extending the whole way through the palate right to the alveolar process. The cleft is always median.

To complete the picture it should, however, be mentioned that there are a few cases in which there is a combination of group I and group III, i.e. a cleft lip with an intact alveolar process but with a median cleft of the soft and/or hard palate (again the exception confirming the rule).

Group I cases need no preliminary orthodontic treatment and are admitted for operation at the age of about 3 months.

Within a week after birth the child in group II is admitted to the Children's Department and orthodontic treatment is started with the aim of bringing the jaw segments into correct alignment. This is achieved by an orthodontic prosthesis constructed for widening the dental arches while external pressure is applied to the premaxillary segment to bring this into correct position.

It has been questioned whether the prosthesis is troublesome for the child to wear. This does not appear to be so. The children cry when it is removed and quiet down as soon as it

is replaced. The prosthesis also makes the feeding easier closing part of the palatal defect. Careful control and adjustment of the prosthesis prevent the formation of pressure sores.

As soon as the orthodontist is satisfied as to the alignment of the dental arch, the child is transferred to the plastic surgery department for operation. The hard palate, the floor of the nostril and the lip are then closed. In the afternoon the child is re-admitted to the pediatric department. The bilateral cases are operated upon in two sessions. Six days after the operation the child is discharged to its home

At the age of two years, the patient is admitted to the Plastic Surgery Department for closure of the soft palate. In the meantime the child has been under the surveillance of the orthodontist, but no major orthodontic treatment is given until the appearance of permanent teeth.

Children with cleft palate only — group III — are also operated upon at the age of two years, and are of minor interest as far as the orthodontist is concerned.

It is a well-known fact that some children with cleft palate are more prone to oto-laryngological disorders than other children. The oto-laryngologist is therefore an important member of the team.

As the child grows older and starts talking the speech therapist comes into the picture to assess possible speech defects and give advice. Speech therapy is started when considered necessary

At the age of five it must be decided whether the child will need an additional operation to achieve an adequate oro-nasal sphincter mechanism. If this is considered indicated, the child is then admitted for operation. At the same operation minor labial corrections may be carried out.

In the following years the child should be regularly studied and examined by the team. The orthodontic member is usually the most active in this period, guiding the erupting teeth into normal position.

Final correction of the lip and the nose including submucous resection of the nasal septum, is delayed until the age of 14—15 depending on the physical development of the child.

A retention bridge to maintain the dental arch is not permanently constructed until the age of 18. Then — and only then — can the result of the treatment be finally assessed.

23 The Turner Phenotype in Three Brothers with Ichtyosis Vulgaris

S. SIMILA and U KASKI

Department of Pediatrics, Oulu University

Turner s syndrome appears mostly in phenotypic females. Its characteristics were described by Turner short stature webbing of the neck cubitus valgus and sexual infantilism. There are also other somatic anomalies.

The Turner phenotype in the male is far less common Lenz (7) estimates the insidence ratio in men and women at 1 10

The Turner phenotype in man corresponds clinically to Turner s syndrome but exhibits more often mental retardation, ocular deformities, and cardiac anomalies (3) The gonadal development ranges from normal to complete gonadal agenesis (3)

The etiology of Turner s syndrome in the female usual karyotype 45/XO or less frequently sex chromosomal mosaicism or translocation is easily understood from x-chromosomal non disjunction or dissolution The karyotype of the male counterpart is usually normal, 46/XY sometimes with x-chromosomal mosaicism or aberrant x-chromosomes Modern cytogenetic research therefore, cannot explain the etiology of Turner's phenotype in the male merely as a chromosomal aberration

The Turner phenotype may occur familially It has been described in two brothers (1) in a sister and brother (8 9) and in two sisters (2 4 5) The present case involved four brothers, three with a typical Turner phenotype No consanguinity was present in the two preceding generations, and the boys mother had had no miscarriages.

The three brothers showed the following typical stigmas short stature, webbing of neck cubitus valgus, low hairline low set ears, shield like chest, and various other skeletal anomalies. Their karyotype was normal 46/XY The younger two had unilateral kryp-

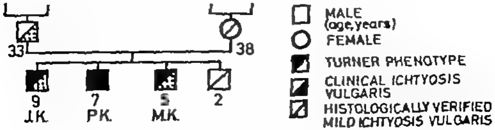

TABLE I PEDIGREE OF THE FAMILY

torchism. The penis, palpable testes, excretion of 17-ketosteroids and gonadotropins were normal and related to age. Mental development was normal, and no renal or vascular anomalies were noted. Mother father and the youngest brother were clinically healthy

The boy of 7 had clinically established and histologically verified ichtyosis vulgaris. The skins of the 9- and 5-year old brothers appeared clinically healthy but mild histological alterations suggestive of ichtyosis vulgaris were traced. The father's skin exhibited similar histological findings, whereas the mother and the youngest son had clinically and histologically normal skins.

The ichtyosis vulgaris of the present family suggests the autosomal dominantly inherited form rather than the sex linked, recessive type. Its dominant inheritance seems irregular and incomplete (6)

The strongly familial Turner phenotype in this family suggests an x chromosomal or autosomal recessive type of inheritance. Unfortunately the irregularly dominant inheritance of ichtyosis vulgaris provides no further clues as to its etiology There may therefore, exist no single etiologic factor responsible for the Turner phenotype in males.

24 Hyperprolinemia without Renal Disease

S. SIMILA and J. K. VISAKORPI

Department of Pediatrics, University of Oulu and Children's Hospital, University of Helsinki

Hyperprolinemia is a rare inborn defect of metabolism. Efron (1) has demonstrated that apparently two types of this disease exist: type I is a defect of proline oxidase enzyme and type II a defect of PC-dehydrogenase. A description is given here of a family with four living children of which two were suffering from hyperprolinemia type II (Fig. 1).

The index case, a boy, was admitted at the age of 6 months; he had had prolonged epileptic seizures. His birth and early development were normal. On admission, the patient was flabby, somnolent and hyperthermic. On the second day an erythematous rash appeared. The seizures subsided within three days under antiepileptic treatment. Few pathological findings were made on laboratory examination, although the EEG was extremely abnormal. Strong prolin, hydroxyprolin and glycinuria were found in biochemical studies. The serum proline concentration was 398 mikrog/ml. After the discovery of this metabolic anomaly the whole family was examined. The oldest child in the family had died at the age of 4½ years, following severe convulsive disorders and progressive mental retardation from the age of 6 months. The parents and other living children were all healthy, although a boy aged 7 had also had a metabolic anomaly similar to the index case. His serum proline concentration was 334 mikrog/ml. The EEG was also pathological. The mother and twin sisters aged 10 had a slightly increased excretion of glycin, but normal serum proline.

In the family described, one boy suffered from symptomatic hyperprolinemia; the symptoms were convulsive disorders and rash without renal disease. Another boy in the family had died, probably of the same disease. The third boy suffered from subclinical hyperprolinemia. The metabolic findings were typical hyper

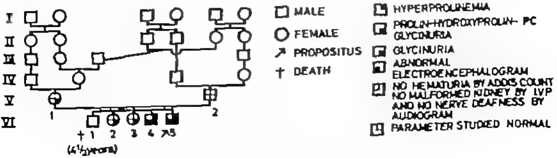

Fig. 1. Pedigree of the family described

prolinemia, hydroxyprolin-prolin-glycinuria and pyrrolidonecarboxylicacid in excess in the urine. Both girls in the family as well as the mother had slight glycinuria, and only the father was completely normal biochemically. It is possible that this disease is inherited by sexlinked, recessive mode, and the slight glycinuria is probably a heterozygotic manifestation. The explanation of this glycinuria is not clear: it is not explicable in the same way as the glycinuria in hyperprolinemic individuals.

The index patient was put on a prolin-poor diet. After a diet period of six months the serum prolin was still high, but the patient's clinical condition had improved, and the EEG was normal.

25 Effects of Beta Adrenergic Blockade on Heart Rate and Blood Lactate in Children during Maximal and Submaximal Exercise

C. THORÉN

Department of Pediatrics, Kronprinsessan Lovisas Barnsjukhus, Stockholm.

Hemodynamic studies in adults with beta-adrenergic blocking agent have been reported in recent years (1, 2, 3). During submaximal work heart rate decreases 10—20 % and with unchanged stroke volume the cardiac output also decreases but with increasing A—V oxygen difference. Studies of heart rate after beta-blockade at maximal and exhausting exercise and blood lactate production have not been reported, nor any studies of the cardiac response in childhood.

Material and Method

11 healthy schoolboys in 2 age groups, 9 and 11, have been studied before and one hour after 10 mg propranolol (Inderal®) was given by oral administration before breakfast. The studies were done on 2 different days. Heart rate was recorded by ECG at rest in

The metabolic findings were typical hyper

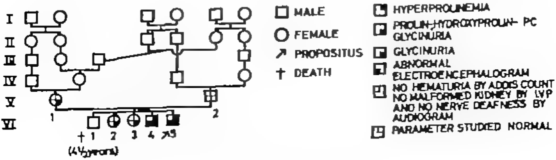

Fig 1 Pedigree of the family described.

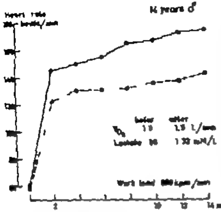

Fig. 1 Heart rate during prolonged submaximal work before and after propanolol.

the continuous increase of heart rate was diminished after propranolol (Fig 1) Despite unchanged work intensity the oxygen uptake decreased as well as the blood lactate.

In cases with abnormal orthostatic reaction per oral Inderal abolished both ECG-change and tachycardia, and has successfully been used in long term treatment.

The results show that children can perform the same exercise at submaximal and maximal intensity after beta-adrenergic blockade with significantly decreased heart rate and lesser lactate production. This means a better oxygen utilisation in the muscular metabolism and results in work on a more aerobic level.

supine position and after 6 minutes periods on a bicycle ergometer at fixed work loads, 200 300 and 400 kpm/min Individual load was given for maximal work to exhaustion The maximal heart rate and the rate one minute after in supine position were recorded In all cases blood lactate was determined during the tests.

RESULTS

In table I the mean values of heart rate and lactate in the two groups are given The heart rate decreased significantly after propranolol, with 12—16% during submaximal work and 11—13% of the maximal heart rate. The degree of decrease was the same in both age groups and there was still a linear increase with the work load

At rest and during aerobic work the blood lactate was significantly lower in the 11 year age group after beta blockade

The maximal lactate values which were lower than in adults, decreased 29 and 25% in the two groups. The differences between mean values were, however not significant, although the individual differences were probably significant ($p < 0.05$) The systolic blood pressure during work was not significantly decreased The respiratory frequency the skin temperature and the degree of sweating were unchanged

The capacity to perform the exercise was unchanged and most of the boys found it subjectively easier to work after beta blockade

During prolonged submaximal work

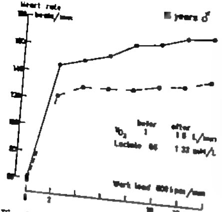

Fig. 1 Heart rate during prolonged submaximal work before and after propanolol.

the continuous increase of heart rate was diminished after propranolol (Fig 1) Despite unchanged work intensity the oxygen uptake decreased as well as the blood lactate.

In cases with abnormal orthostatic reaction per oral Inderal abolished both ECG-change and tachycardia, and has successfully been used in long term treatment.

The results show that children can perform the same exercise at submaximal and maximal intensity after beta adrenergic blockade with significantly decreased heart rate and lesser lactate production. This means a better oxygen utilisation in the muscular metabolism and results in work on a more aerobic level.

26 Recording of Intratracheal Pressure during Intermittent Positive Pressure Ventilation in the Newborn

E. K. VAPAAVUORI

University Children's Hospital, Helsinki

Many studies on the pressure volume relationships of normal and abnormal human lungs have been recently reported, but the intratracheal pressure changes during assisted ventilation using positive-pressure respirators are not known. The purpose of this exhibit is to present some intratracheal pressure recordings correlated with clinical symptoms and X-ray findings. The pressure recordings have been obtained in 25 newborn infants re-

quiring artificial ventilation and treated in the Neonatal Intensive Care Unit of University Children's Hospital Helsinki

In order to measure intratracheal pressure directly an open-ended Nr 5 F feeding catheter was attached to the endotracheal tube Using the BENNETT respirators type PR 1 and PR 2 the intratracheal pressure was measured by connecting the catheter filled with saline solution to a pressure transducer an electromanometer and a recorder The recordings were obtained on systemic Bennett pressures of 20 30 and 40 cm of water and on frequencies of 40 60 and 80 cycles per minute.

According to the pressure volume characteristics and the degree of atelectasis of the lungs, significantly different types of pressure curves were recorded The shape of the pressure curve and the duration of the pressure plateau were the most marked differences between the curves in 6 different clinical syndromes. Thus intratracheal pressure recording during intermittent positive pressure breathing may be used as a diagnostic aid when severe neonatal pulmonary pathology occurs In addition, continuous monitoring of intratracheal pressure during artificial respiration is a simple and effective clinical method for demonstrating the patency of the ventilatory system

SUMMARY

Intratracheal pressure changes during artificial respiration in different types of respiratory insufficiency of the newborn were recorded and the characteristics of the pressure curves are correlated with clinical findings. It is suggested that these pressure tracings could be used for diagnostic purposes and for continuous monitoring of artificial ventilation

27 Virus Isolations from Children with Acute Respiratory Illness

A Comparison of a Family Study Group and a Group of Nursery Infants

L. VIHMA

Department of Virology and Children's Hospital, Turku University

The present study was carried out in Turku city over a period of 2 years, on two different groups.

The number of the families in the family group was 29 from September 1965 to December 1965 28 from January to March 1966 43 from April to early May 1966 42 from late May to August 1966 40 in September 1966 39 from October 1966

to early January 1967 and 38 since January 15, 1967 The number of children under school age in the family group was 59 56, 92, 89 85 84 81 respectively All the families had at least three children, the youngest one being an infant. All the infants and small children in the family group were nursed in their homes.

The other group consisted of children in a private nursery in Turku city The nursery has 15 beds. During the observation period from September 1965 to May 1967 a total of 50 infants were resident.

For virus isolation pharyngeal swabs were taken at the beginning of each respiratory illness. Specimens were inoculated directly into cell culture tubes. Two tubes of HeLa, primary monkey kidney and U cells were inoculated with each specimen. Tissue culture tubes were incubated at 35 C for two weeks. A clinical examination and diagnosis of each child was made

A total of 311 virus isolations were made of 532 cases of respiratory illness reported (24 % positive) From the family group 381 respiratory illnesses were reported with 84 virus isolates (22% positive) From the nursery group 171 illnesses were reported with 48 virus isolates (27% positive)

Among the agents isolated in the family group were respiratory syncytial (RS) virus (22 strains) parainfluenza type 3 (11 strains) adenovirus type 1 (12 strains) adenovirus type 2 (6 strains) adenovirus type 3 (7 strains) adenovirus type 5 (5 strains) adenovirus type [illegible] (3 strains) adenovirus type 7 (4 strains) and herpes simplex (7 strains)

In the nursery group the isolates were RS virus (14 strains) parainfluenza type 3 (1 strain) adenovirus type 1 (7 strains) adenovirus type 2 (11 strains) adenovirus type 5 (12 strains) adenovirus type 6 (2 strains) and Coxsackie B_3 (4 strains) RS virus was isolated simultaneously with adenovirus, type 2 or type 5, in 2 cases from the family group and in 4 cases from the nursery group

RS virus isolates in the family group were obtained during the autumn both in 1965 and in 1966 and in 1967 during the first three months but in the nursery group only in February 1967 Parainfluenza type 3 was isolated in the spring of 1966 in both groups but in the autumn of 1966 only in the family group Adenovirus types 1 2 and 5 were isolated in both study groups. The epidemic of adenovirus type 3 in the family group did not occur in the nursery Neither was adenovirus type 7 isolated in the nursery group

quiring artificial ventilation and treated in the Neonatal Intensive Care Unit of University Children's Hospital Helsinki

In order to measure intratracheal pressure directly an open ended Nr 5 F feeding catheter was attached to the endotracheal tube. Using the BENNETT respirators, type PR 1 and PR 2 the intratracheal pressure was measured by connecting the catheter filled with saline solution to a pressure transducer an electromanometer and a recorder The recordings were obtained on systemic Bennett pressures of 20 30 and 40 cm of water and on frequencies of 40 60 and 80 cycles per minute

Contents

INTRODUCTION

Since severe acute respiratory disease in infants is a worldwide public health problem which has far exceeded that of poliomyelitis and many other infectious illnesses in mortality it is clear that an understanding of the etiology and epidemiology of this disease is of primary importance. Over the past 15 years, advances in laboratory methodology have contributed to the discovery and classification of a large number of hitherto unrecognized nonbacterial pathogens from the respiratory tract. The respiratory syncytial (RS) virus was isolated in 1956 and its importance in acute human respiratory disease was definitely documented a few years later It has proved the most important single cause of pneumonia and bronchiolitis in infants and small children.

The present paper is intended to provide information on the incidence, prevalence and spread of RS virus infection in an urban community in Finland (Turku) and also to some degree in the capital of the country (Helsinki) It also describes respiratory and otological disease manifestations due to infection with RS virus. The experimental studies to be presented were concerned with the question of reproduction of RS virus in the guinea pig middle ear with the development of a method of producing specific hyperimmune RS virus antiserum, and with the specific precipitin response following inoculation of the agent.

INTRODUCTION

INTRODUCTION

Since severe acute respiratory disease in infants is a worldwide public health problem which has far exceeded that of poliomyelitis and many other infectious illnesses in mortality it is clear that an *understanding of the etiology and epidemiology* of this disease is of primary importance. Over the past 15 years, advances in laboratory methodology have contributed to the discovery and classification of a large number of hitherto *unrecognized nonbacterial pathogens* from the respiratory tract The respiratory syncytial (RS) virus was isolated in 1956 and its importance in acute human respiratory disease was definitely documented a few years later It has proved the most important single cause of pneumonia and bronchiolitis in infants and small children.

The present paper is intended to provide information on the incidence, prevalence and spread of RS virus infection *in an urban community in Finland* (Turku) and also to some degree in the capital of the country (Helsinki) It also describes respiratory and otological disease manifestations due to infection with RS virus. The experimental studies to be presented were concerned with the question of reproduction of RS virus in the guinea pig middle ear with the development of a method of producing specific hyperimmune RS virus antiserum, and with the specific precipitin response following inoculation of the agent.

REVIEW OF THE LITERATURE

Discovery of the virus: first isolation from man; isolation from unfrozen specimens

In 1956 Morris and associates (46) described the first recovery of a virus, which they termed chimpanzee coryza agent (CCA), from the respiratory secretions of laboratory chimpanzees with coryza and established a presumptive etiological association between the new agent and the acute respiratory illness of a laboratory worker who had had close contact with the animals. The next year *Chanock and his associates* (14, 18) reported the isolation of two virus strains, indistinguishable from CCA, from infants with lower respiratory tract infection and suggested these isolates and the CCA be grouped together and named the respiratory syncytial (RS) virus. In 1960 Beem *et al.* (9) observed that the recovery of RS virus from throat swabs is highly facilitated when the specimens are inoculated into tissue culture without prior freezing and thawing and by this means succeeded in isolating the agent from not less than 41 patients with acute respiratory illness.

Laboratory diagnosis

The diagnosis by virus isolation is usually made by culturing the agent from a sample of *throat secretion*. Several studies of subjects with acute respiratory infection (1, 5, 9, 12, 15, 27, 35, 43, 57, 59) show that RS virus may be recovered with high frequency from young children, and with the highest frequency from infants in the first 6 months and year of life, and thereafter more rarely with increasing age. Some researchers (1, 9, 43, 57) have recovered the agent infrequently or not at all from children of more than approximately 5 to 6 years of age. It is not known whether this indicates less likelihood of isolating RS virus from older infected children, or whether the infection rates of older children are very much lower.

The first RS virus isolation from an adult person was reported by Beem *et al.* (9) *who recovered the virus from* a 35-year-old man. Subsequently Hamre and her associates (32, 33) succeeded in isolating RS virus from 15 medical students with common colds. Johnson and his associates (37) recovered 4 strains of RS virus from recruits in an infantry training regiment. In a study of human adult volunteers experimentally infected with the agent, virus shedding was noticed in a considerable number of cases (38, 40). Jamieson *et al.* (36) reported positive isolations from 3 adult persons of whom *the oldest was 76 years old. These and* other studies (6, 39) indicate that adults and children may acquire symptomatic RS virus reinfection with associated positive isolations despite the presence in

the serum of specific neutralizing antibody to a moderate or high titer. Likewise it has been shown that young infants are susceptible to RS virus and may acquire primary infection and shed virus despite the presence of circulating specific neutralizing antibody transmitted from the mother (11). Chanock stated (16) that the inability of the serum neutralizing antibody to effectively prevent and modify RS virus infection depends on the property of this agent to spread and replicate primarily in the superficial epithelium of the respiratory tract.

The complement fixation (CF) test has been employed more extensively than the neutralization test as a serodiagnostic method of detecting RS virus infection because of its greater simplicity and ease of performance. Both tests have proved somewhat insensitive as a means of demonstrating infection in young infants under 3 to 6 months of age (7, 9, 14, 15, 28, 47, 60). Studies show that the neutralization test is more capable than the CF test in detecting diagnostic antibody rises in children in this young age group (14, 15, 47), but that the sensitivity of the latter can be improved by increasing the amount of CF antigen from 4 to 8 units (15, 39, 51). Ross et al. (51) emphasized the importance in obtaining a good CF antigen of incubating the tissue cultures for prolonged periods after the development of the complete cytopathic effect, and moreover stated that the optimal time for the collection of convalescent serum from very young infants is between the 4th and 6th week of illness. Chanock et al. (14) pointed out the necessity of a low initial serum dilution of preferably 1/4 or 1/2 in the titration of CF antibody in sera from young children.

RS virus infection in adults may not always be accompanied by a measurable serological response. Out of 30 adult volunteers who contracted infection as indicated by positive isolations after intranasal administration of RS virus, 12 failed to develop increased antibody titers (38). In the study of natural RS virus infections among college students (33), 4 subjects from whom virus was recovered likewise showed no increase in antibody. In both these studies, the antibody responses occurred predominantly in subjects who developed clinical illness. According to Johnson et al. (38), there seems to be an association between the extent of RS virus infection in adults as measured by the serological response and the occurrence of respiratory disease. The CF and neutralization tests have proved roughly equally reliable in the serodiagnosis of adult RS virus infection (33, 38). It is noticeable that the adult volunteers did not show significant rises in antibody titer until 14 to 18 days after inoculation (38).

Antigenic strain variations

Experimental studies and studies of human convalescent sera have shown that different RS virus strains share a common CF antigen (20, 2?, 57, 60). This has highly facilitated serodiagnostic procedures using the CF technique, since potent CF antigen prepared from any strain can be expected to have the capacity of fixing complement with the antibody formed in the course of every RS virus infection.

However, antigenic differences do oc

REVIEW OF THE LITERATURE

Discovery of the virus first isolation from man isolation from unfrozen specimens

In 1956 Morris and associates (46) described the first recovery of a virus, which they termed chimpanzee coryza agent (CCA) from the respiratory secretions of laboratory chimpanzees with coryza and established a presumptive etiological association between the new agent and the acute respiratory illness of a laboratory worker who had had close contact with the animals. The next year Chanock and his associates (14 18) reported the isolation of two virus strains, indistinguishable from CCA from infants with lower respiratory tract infection and suggested these isolates and the CCA be grouped together and named the "respiratory syncytial" (RS) virus. In 1960 Beem *et al* (9) observed that the recovery of RS virus from throat swabs is highly facilitated when the specimens are inoculated into tissue culture without prior freezing and thawing and by this means succeeded in isolating the agent from not less than 41 patients with acute respiratory illness.

Laboratory diagnosis

The diagnosis by virus isolation is usually made by culturing the agent from a sample of throat secretion Several studies of subjects with acute respiratory infection (1 5 9 12 16 27 35 43 57 59) show that RS virus may be recovered with high frequency from young children, and with the highest frequency from infants in the first 6 months and year of life, and thereafter more rarely with increasing age. Some researchers (1 9 43 57) have recovered the agent infrequently or not at all from children of more than approximately 5 to 6 years of age. It is not known whether this indicates less likelihood of isolating RS virus from older infected children, or whether the infection rates of older children are very much lower

The first RS virus isolation from an adult person was reported by Beem *et al* (9) who recovered the virus from a 35 year-old man Subsequently Hamre and her associates (32 33) succeeded in isolating RS virus from 15 medical students with common colds. Johnson and his associates (37) recovered 4 strains of RS virus from recruits in an infantry training regiment In a study of human adult volunteers experimentally infected with the agent virus shedding was noticed in a considerable number of cases (38 40) Jamieson *et al* (36) reported positive isolations from 3 adult persons of whom the oldest was 76 years old. These and other studies (6 39) indicate that adults and children may acquire symptomatic RS virus reinfection with associated positive isolations despite the presence in

RS virus infection and respiratory ill ness in a study comprising children from an outpatient clinic. Later Beem *et al.* (9) confirmed this observation additionally providing evidence that RS virus infection is etiologically firmly associated with respiratory illness and particularly with bronchiolitis and pneumonia in infants. The important role of this agent as a cause of upper and lower respiratory disease in infants and children has subsequently been documented in a series of investigations (8, 15 17 23 30 44, 47 49 52) Kapikian *et al.* (39) showed that RS virus pneumonia occurs about equally as often in infants with pre-illness neutralizing antibody as in those without Hilleman *et al* (34) and Chanock *et al* (16) who estimated the relative importance of various viruses in acute respiratory disease showed, in studies extending over a period of several years, that RS virus is apparently responsible for the greatest part of total respiratory illness in infancy and early childhood. They concluded that this agent is the most important single definable viral pathogen in the respiratory tract during early life

RS virus has proved the most common definable agent in the bronchiolitis syndrome (2, 5 8, 9 1 15 17 41 43 47—50 53) According to Chanock (16) it also causes pneumonia more frequently than other viruses, bronchitis and upper respiratory infection to about the same extent as a number of other viral agents, but croup comparatively infrequentl RS virus has been shown to produce respiratory disease with highest frequency during the first 6 months of life a unique property not shared by other respiratory pathogens (16)

Holzel *et al.* (35) cultured *Haemophilus influenzae* significantly more frequently from children with RS virus infection than from other groups of subjects. However bacteriological examinations carried out in a number of other studies (8 9 14, 44 46 47 49 55) have failed to reveal data which would establish any causal connection between a bacterial pathogen and the development of bronchiolitis or pneumonia in subjects infected with RS virus. These findings are in agreement with the observation of Field *et al.* (25) in a double-blind trial, that treatment with antibiotics did not accelerate or otherwise influence the recovery of children from epidemic bronchiolitis etiologically linked with RS virus.

Deaths have been reported among infants of 12 months of age or younger with confirmed or probable RS virus infection (—4 9 16 21 26 27 35 41) A review reveals that 26 % of all the children who died were also suffering from some abnormal complication such as congenital heart disease mongolism or burns. According to Cortes and Chanock (21) the mortality rate may be as high as 2.4 % among RS virus-positive hospitalized patients.

Since maternal RS virus antibodies are apparently transmitted to the newborn (7 14 28 30 44) 50 % or more of all infants less than 3 months old are mainly for this reason seropositive to RS virus. After the disappearance of the maternal antibodies by the 4th to 8th month of age, the proportion of seropositive individuals increases with age About 80 to 100 % of 4 to 6 year-old children have neutralizing antibody for RS virus (7 14 30 4., 54 57 59) These

cur between strains of RS virus, as demonstrated in cross neutralization tests with ferret sera obtained 3 to 4 weeks after inoculation of virus by the intranasal route (20 22) In these experiments by Coates and her associates, animals infected with the prototype (Long) RS virus, isolated in 1956 developed homologous neutralizing antibody titers which were 4 to 64 fold higher than titers to a strain (CH 18537) isolated in 1962. The antigenic differences were reciprocal as 3 out of 4 animals infected with the CH 18537 strain developed no detectable heterologous antibody although the homologous titers were 1/32 to 1/64 Reinfection of the animals with the homologous strain resulted in the development of heterologous antibody with little or no change in the homologous antibody titer The existence of antigenic differences between RS virus strains was subsequently again demonstrated by Wulff et al (60) in cross neutralization tests with rabbit and monkey sera obtained after parenteral virus inoculations. However in contrast to Coates et al (20 22) these investigators never achieved an increase in the low titer to the heterologous strain even after 3 reimmunization cycles. Using sera obtained from guinea pigs inoculated with virus by the intranasal route Suto et al (57) recently demonstrated antigenic dissimilarities between the Long strain of RS virus and a strain isolated in Japan Antigenic analysis of RS virus isolates by the plaque reduction neutralization test using post infection ferret sera has shown that most isolates, although reasonably closely related can be distinguished from each other but that there are some strains, such as the CH 18537 isolated in the U.S.A. and the 8/60 strain isolated in Gothenburg Sweden which differ essentially by reason of their antigenic properties from most of the other RS viruses studied (19 24) It is of interest to note that several antigenically distinguishable RS viruses may be active during the same outbreak. Coates et al (19) detected no less than 3 antigenically distinguishable patterns among 12 strains isolated during a single epidemic in the U S.A. in 1964 The Randall strain used throughout the present study and the Long strain have proved antigenically identical or closely related (9 10 24)

While ferrets and guinea pigs respond to primary instranasal RS virus inoculation by the development of homologous but not heterologous neutralizing antibody infants primarily infected with RS virus presumably develop both homologous and heterologous antibody This contention is based upon the observation by Wulff et al (60) and Ross et al (51) that young infants with probable primary RS virus infection produce significant amounts of neutralizing antibody against both the local and prototype strains. However in most cases the antibody showed somewhat higher titers for the local strain On the basis of their antigenic analysis of RS virus, Coates et al (19) concluded that the agent apparently resembles the A or A famlies of influenza A virus in the extent of antigenic heterogeneity

Importance in etiology of acute respiratory illness

Chanock and Finberg (14) first suggested the association between human

OBJECT OF THE STUDY

The studies on human subjects dealt with

- the incidence of RS virus infection over a prolonged period of study among children in an urban community (Turku) in Finland (I, III VIII XI)
- the symptoms and signs in RS virus-infected hospitalized children the division of these children into various disease categories by age, and into various groups according to place of residence prior to admission (I II VIII)
- the relative importance of RS virus-associated severe acute respiratory disease as an indication for hospitalization during outbreaks caused by this agent among children in Finland (I II III VIII)
- the evaluation of the virus isolation technique using a direct inoculation method as compared with the CF test as a means of detecting RS virus infection in children of various ages (I VIII)
- the numbe f solation specimens required for a positi e diagnosis, and the proportion of specimens yielding virus at various phases of disease (VIII)
- the role of RS virus in otitis media in children (IV V VIII XI)
- the incidence and spread of RS virus infection among the children of a selected nursery over a prolonged period of study (III)
- the occurrence and spread of RS virus infection in families (IX)

The experimental studies carried out concentrated on

- the susceptibility of the guinea pig middle ear to RS virus, and the development of a virus isolation technique suitable for studies of the otological significance of this virus (VI VII)
- the development of a convenient method of producing high titered RS virus antiserum free from undesired antibody (X)
- the occurrence of precipitating antibodies to RS virus and the identification of the precipitation lines formed by these antibodies (X)

percentage rates apparently represent a minimum estimate of experience gained with the agent during previous years.

Although the role of RS virus in childhood respiratory disease is fairly well understood comparatively little is known regarding the consequences of infection in adults. RS virus reinfection in adults seems to be associated with a mild mostly afebrile illness of the common cold type in the upper respiratory tract (32 33 37 38 40) The data available suggests that adult RS virus infection is relatively infrequent (34) and presumably comparatively unimportant but that it may cause discomfort of clinical significance under certain conditions According to Sommerville (55) and Carilli *et al* (13) RS virus may have a causal or associated role in exacerbations of chronic bronchitis.

Spread of infection

Epidemics of RS virus infection have been reported in a number of countries in North America Europe Australia and Asia. The epidemics usually sharply limited in length and of 2 to 5 months duration, have been reported as recurring at approximately yearly intervals during the fall winter and spring among urban populations, and affecting a great number of infants and young children. According to findings in various parts of the world the peak in serious acute pediatric respiratory disease particularly the peak in bronchiolitis and pneumonia in small infants, coincides annually with the prevalence of RS virus infection (16 17 26 29 47)

Little is known about the conditions for the spread of RS virus at work or among separate groups of people in public life, and the infection risk they are exposed to However RS virus is known to obtain entrance during epidemics to certain institutions such as the nurseries and premature nurseries and to spread quickly among the young occupants with resultant infection rates ranging from 80 to 100 % (11 39 56) Hospital spread of RS virus infection has been shown to occur among pediatric control in patients, as reported by Chanock *et al* (14 15) with infection rates of 42 and 15 % respectively In other studies (9 44) hospital-acquired RS virus infections have been uncommon.

LABORATORY DIAGNOSIS (I, II, III, VIII, IX)

Material and methods

The subjects studied were hospitalized children under 6 years (I VIII) or under 2 years (II) of age. Throat swab specimens were obtained with a dry cotton applicator which was immediately immersed in the maintenance medium of a tissue culture tube after which the fluid remaining in the cotton was pressed out by rubbing the swab along the inner surface of the tube. This method here referred to as the direct inoculation technique was employed throughout the study with minor variations. In the first study (I) 1 applicator alone was used for inoculating 2 tissue culture tubes (BS C1 cells in 5 % calf serum) whereas in the second study (II) 2 tissue culture tubes (U cells in 5 % horse serum) were inoculated each with a separate applicator. Inoculated BS-C1 cultures were examined every alternate day for a period of 4 weeks, and inoculated U cultures every day or every alternate day for a period of 2 weeks.

Variations in CF techniques and blood sampling intervals are apparent from the data listed below.

Results and discussion

The direct inoculation technique seemed disappointing at the beginning of the study (I) since heavy growth of fungi occurred in the inoculated tissue cultures. However it soon appeared that the concentration of amphotericin B (0.025 microg/ml) used was insufficient. After the addition of nystatin (25 units/ml) to the maintenance medium, not a single culture out of the 200 tested (I) was lost because of fungus growth. The concentration of nystatin was subsequently maintained at the level of 25 units/ml, and that of amphotericin B increased to 5 microg/ml (VIII). The presence of the latter drug might have been unnecessary. In any case no fungal contamination was observed when these two antimycotic drugs were used in the concentrations given, and no toxic effect on the tissue cultures was apparent. Overgrowth of bacteria occurred sometimes despite the presence of penicillin and streptomycin in the culture media. About 1 % of the tubes had to be discarded for this reason (I).

The method of inoculating cell cultures

Study No.	Scale	End points. Per cent hemolysis	Units of test antigen	Initial serum dilution	Interval in weeks between 1st and 2nd serum
I	Macro	25	8	1/8	1—2
II	"	50	4	1/4	1—
VIII	Micro	25	3	1/4	1—

A third serum specimen was obtained about 2 weeks after the 1st specimen from most of the subjects of less than 6 months of age.

directly with the throat swabs for isolation of RS virus has been employed infrequently by other investigators (4, 27 35, 51, 56) but with satisfactory results. It would seem that inoculation of tissue cultures by a direct technique, such as the one used in the present study (VIII) would assure a higher amount of virus in the inoculum than the indirect routine technique using a sample of the diluted throat swab contents as inoculum. The direct technique seems to be of particular value in isolating viruses undergoing more or less rapid inactivation during storage, such as the RS virus, since it enables specimens to be inoculated into tissue culture immediately after being taken, this, in addition, contributing to diagnosis at the earliest possible stage. Successful isolation by the direct technique, of course, implies tissue cultures of good quality sensitive to the virus or group of viruses sought. If each tissue culture tube is inoculated with a separate swab as in study No. VIII, and there are several types of cultures to be inoculated, practical difficulties may arise as how to obtain the required number of swabs. Hence, the direct inoculation technique appears particularly suited to the search for single agents (or limited variety of agents) necessitating the use of no more than one type of a highly sensitive cell culture.

The time required for the cytopathic effect (CPE) to become apparent following inoculation of throat swab material varied from 8 to 25 days (mean time 13 days) for the BS-CI cultures (I) and from 3 to 14 days (mean time 6 days) for the U cultures (VIII). Eighty % of the positive U cultures showed a definite CPE within 1 week following inoculation. Although virus growth was probably promoted more efficiently in the U cells due to minor dissimilarities in inoculation and feeding techniques, it is difficult to explain the remarkably faster appearance of CPE in the U cultures solely on the basis of these differences in technique. Characteristically the CPE of the BS-CI cultures consisted mostly of localized syncytial areas, whereas the CPE of the U cultures, for the most part, caused destruction of the entire cell sheet.

Detailed analysis of the isolation results obtained after direct inoculation of U cultures with throat swabs (VIII) revealed that:

1) the likelihood of detecting RS virus infection in children under 6 years of age was highest during the first week of illness (82 % positive specimens) the rate of positive specimens then decreasing during the second (49 %) third (21 %) and fourth (11 %) weeks of illness.
2) all children found to be positive by virus isolation, harboured virus in their throat secretions as early as on the first day of specimen collection, indicating that repeated sampling during subsequent days was unnecessary
3) for a positive diagnosis by virus isolation it was necessary to inoculate more than 1 tissue culture tube (each with a separate swab) The necessity of inoculating more than 1 tissue culture tube was more apparent during the later course of the disease, but even at the acute stage the inoculation of tubes appeared desirable. As many as 14 % of the RS virus infections diagnosed by virus isolation could have remained undetected,

The concentration of nystatin was subsequently maintained at the level of 25 units/ml and that of amphotericin B increased to 5 microg/ml (VIII). The presence of the latter drug might have been unnecessary. In any case no fungal contamination was observed when these two antimycotic drugs were used in the concentrations given and no toxic effect on the tissue cultures was apparent. Overgrowth of bacteria occurred sometimes despite the presence of penicillin and streptomycin in the culture media. About 1 % of the tubes had to be discarded for this reason (I).

The method of inoculating cell cultures

VIII	Micro	–3	8	1/4	1—

A third serum specimen was obtained about 5 weeks after the 1st specimen from most of the subjects of less than 6 months of age

directly with the throat swabs for isolation of RS virus has been employed infrequently by other investigators (4, 27 35, 51 56) but with satisfactory results. It would seem that inoculation of tissue cultures by a direct technique, such as the one used in the present study (VIII) would assure a higher amount of virus in the inoculum than the indirect routine technique using a sample of the diluted throat swab contents as inoculum. The direct technique seems to be of particular value in isolating viruses undergoing more or less rapid inactivation during storage, such as the RS virus, since it enables specimens to be inoculated into tissue culture immediately after being taken, thus, in addition, contributing to diagnosis at the earliest possible stage. Successful isolation by the direct technique, of course, implies tissue cultures of good quality sensitive to the virus or group of viruses sought. If each tissue culture tube is inoculated with a separate swab as in study No VIII and there are several types of cultures to be inoculated, practical difficulties may arise as how to obtain the required number of swabs. Hence, the direct inoculation technique appears particularly suited to the search for single agents (or limited variety of agents) necessitating the use of no more than one type of a highly sensitive cell culture.

The time required for the cytopathic effect (CPE) to become apparent following inoculation of throat swab material varied from 5 to .. days (mean time 13 days) for the BS-C 1 cultures (I) and from 3 to 14 days (mean time 6 days) for the U cultures (VIII). Eighty % of the positive U cultures showed a definite CPE within 1 week following inoculation. Although virus growth was probably promoted more efficiently in the U cells due to minor dissimilarities in inoculation and feeding techniques, it is difficult to explain the remarkably faster appearance of CPE in the U cultures solely on the basis of these differences in technique. Characteristically the CPE of the BS-C1 cultures consisted mostly of localized syncytial areas, whereas the CPE of the U cultures, for the most part, caused destruction of the entire cell sheet.

Detailed analysis of the isolation results obtained after direct inoculation of U cultures with throat swabs (VIII) revealed that

1) the likelihood of detecting RS virus infection in children under 6 years of age was highest during the first week of illness (82 % positive specimens) the rate of positive specimens then decreasing during the second (49 %) third (21 %) and fourth (11 %) weeks of illness.
2) all children found to be positive by virus isolation, harboured virus in their throat secretions as early as on the first day of specimen collection, indicating that repeated sampling during subsequent days was unnecessary
3) for a positive diagnosis by virus isolation it was necessary to inoculate more than 1 tissue culture tube (each with a separate swab) The necessity of inoculating more than 1 tissue culture tube was more apparent during the later course of the disease, but even at the acute stage the inoculation of 2 tubes appeared desirable. As many as 14 % of the RS virus infections diagnosed by virus isolation could have remained undetected,

had only 1 throat swab been taken from each child shortly after hospitalization for the inoculation of only 1 tissue culture tube.

In the first study (I) virus isolation specimens were obtained from 76 children all of whom had acute respiratory illness RS virus was isolated from 7 out of 11 (64 %) subjects with bronchiolitis, 7 out of 14 (50 %) with pneumonia 6 out of 28 (21 %) with bronchitis and 3 out of 23 (13 %) with infection of the upper respiratory tract Similar results have been obtained by other investigators (9 15) all indicating the association of severe respiratory disease with RS virus infection. It can be noted that the association rate was highest for the bronchiolitis syndrome which is again in agreement with the findings of others (9 15 17) The rate of positive isolations decreased with age, as also shown previously (9 15 47) A noticeable feature was that the agent was recovered from no less than 5 out of 7 (70 %) of the infants under 3 months of age suggesting its importance as a cause of infection in the first stages of life (I)

The documented low titered and slow antibody response of very young infants to RS virus infection was also investigated to some degree in the present study (I II) In the first study (I) none of the <3 month-old subjects showed significant (4-fold or greater) rises in CF titer for RS virus, although an RS virus isolation was obtained from some of them. These findings are not surprising as the interval between the paired serum specimens was only 1 to 2 weeks and the serum titrations were initiated from a comparatively high (1/8) dilution. In the second study (II) which was for the main part a serological study the s[…] were collected at an identical inter[…] but the CF titrations were initiat[…] from a 1/4 dilution Of the 25 infa[…] of <3 months of age tested, 3 (12 %[…] showed a significant CF antibody r[…]sponse to RS virus. However not ev[…] this number would have shown a signi[…]icant rise in titer had the serum titration been initiated from a 1/8 dilution, since the convalescent titers never exceeded 1/8. In contrast the convalescent titers of the children of 1 year or over always exceeded 1/8 A comparison revealed that 19 subjects out of 35 (54 %) in the age group 3 — <6 months had significant titer rises, as compared with 26 out of 39 (67 %) in the age group 6 — <12 months and 11 out of 20 (55 %) in the age group 12 — <24 months. The actual rate of RS virus infection among those of <3 months of age remained unknown as virus isolation specimens were not taken but was probably higher than the 12 % observed. The fact that no less than 8 of the <3 month-old infants developed a weak rise in titer from $<1/4$ to 1/4 or from 1/4 to 1/8, speaks in favor of this assumption. On the basis of the results it could be concluded that convalescent serum specimens should not be obtained from infants of <3 months of age, before the 5th week of illness, and that titration of their RS virus CF antibody should preferably be initiated from a serum dilution of 1/4 or lower

In a study of the family members of children with RS virus infection (IX) 7 parents were shown to develop significant CF antibody titer rises to the agent of from $<1/4$ to 1/8 or from $<1/4$ to 1/16 With the reservation that

the paired sera were possibly not appropriately timed and that the number of cases with significant rises in titer was small, the findings demonstrate a surprisingly low-titered CF antibody response to RS virus infection in adults in the age group 20 to 30 years.

The relation between the concentration of antigen required for optimal sensitivity of the CF test and the age of the subjects studied was not investigated in the present study. However, one observation was made with relevance to this question (III). Appropriately timed sera from 10 nursery infants with verified RS virus infection (positive virus isolations) were examined for CF antibody to RS virus in the same test. Nine of the children were most probably suffering from primary infection and were under 4 months of age. One was 4 months old and had a proved reinfection. By accident, the sera were tested with an antigen clarified by centrifugation and stored at +4 C for several months having lost most of its CF activity. This antigen failed to fix complement with the convalescent sera from the 9 primarily infected children, but revealed a rise in titer from < 1/4 to ≧1/64 in the reinfected child. These findings suggest, that besides age, previous experience with the agent may also be a factor determining the concentration of antigen required in the CF test.

Attempts were made to estimate the sensitivity of the isolation method and the CF test as a means of detecting RS virus infection (I, VIII). The results of the latter study (VIII) will be dealt with in more detail. In order to render the CF method more sensitive, a third serum specimen was collected from a great proportion of the < 6 month-old subjects about 5 weeks after the initial one, and 8 antigen units were employed in the tests. As previously outlined, 2 U cell cultures were directly inoculated, each with one of 2 throat swabs, shortly after admission. A retrospective study revealed that out of 22 children of 3 months to < 6 years of age with a significant rise in CF titer 19 (86 %) had a positive virus isolation. Of the 3 CF positive children who failed to yield virus, one was 3 months old and already at the convalescent phase of infection at the time of sampling, the age of the 2 others being 5 years. The findings seem to reflect increasing difficulties in isolating RS virus from children of 5 years or over and are, in this respect, in agreement with the experience of others (1, 43, 57). On the basis of the results it would appear that the efficiency of the isolation method used in the present study in detecting acute RS virus infection in children under 6 years of age is between 86 and 100 %.

To determine the diagnostic efficiency of the CF test, 22 children of from 1 month to < 6 years of age with positive RS virus isolations were kept under observation for the development of a subsequent rise in titer. Nineteen developed a significant antibody response, while 3 failed to do so. The latter were 1, 2 and 11 months old respectively. The results showed a diagnostic efficiency for the CF test of 86 % for all children (similar to that of the isolation method) and of 100 % for those of 1 year or over. The isolation method was thus highly efficient in detecting infection in subjects under 5 years, and the CF test in subjects of 1 year or over.

had only 1 throat swab been taken from each child shortly after hospitalization for the inoculation of only 1 tissue culture tube.

In the first study (I) virus isolation specimens were obtained from 76 children all of whom had acute respiratory illness RS virus was isolated from 7 out of 11 (64 %) subjects with bronchiolitis, 7 out of 14 (50 %) with pneumonia, 6 out of 28 (21 %) with bronchitis and 3 out of 23 (13 %) with infection of the upper respiratory tract Similar results have been obtained by other investigators (9 15) all indicating the association of severe respiratory disease with RS virus infection It can be noted that the association rate was highest for the bronchiolitis syndrome which is again in agreement with the findings of others (9 15 17) The rate of positive isolations decreased with age, as also shown previously (9 15 17) A noticeable feature was that the agent was recovered from no less than 5 out of 7 (70 %) of the infants under 3 months of age suggesting its importance as a cause of infection in the first stages of life (I)

The documented low titered and slow antibody response of very young infants to RS virus infection was also investigated to some degree in the present study (I II) In the first study (I) none of the < 3 month-old subjects showed significant (4-fold or greater) rises in CF titer for RS virus, although an RS virus isolation was obtained from some of them. the paired sera were possibly not appropriately timed and that the number of cases with significant rises in titer was small, the findings demonstrate a surprisingly low-titered CF antibody response to RS virus infection in adults in the age group 20 to 30 years.

The relation between the concentration of antigen required for optimal sensitivity of the CF test and the age of the subjects studied was not investigated in the present study. However, one observation was made with relevance to this question (III). Appropriately timed sera from 10 nursery infants with verified RS virus infection (positive virus isolations) were examined for CF antibody to RS virus in the same test. Nine of the children were most probably suffering from primary infection and were under 24 months of age. One was 24 months old and had a proved reinfection. By accident, the sera were tested with an antigen clarified by centrifugation and stored at +4 C for several months having lost most of its CF activity. This antigen failed to fix complement with the convalescent sera from the 9 primarily infected children, but revealed a rise in titer from <1/4 to ≧1/64 in the reinfected child. These findings suggest, that besides age, previous experience with the agent may also be a factor determining the concentration of antigen required in the CF test.

Attempts were made to estimate the sensitivity of the isolation method and the CF test as a means of detecting RS virus infection (I, VIII). The results of the latter study (VIII) will be dealt with in more detail. In order to render the CF method more sensitive, a third serum specimen was collected from a great proportion of the <6 month-old subjects about 5 weeks after the initial one, and 8 antigen units were employed in the tests. As previously outlined, 2 U cell cultures were directly inoculated, each with one of 2 throat swabs, shortly after admission. A retrospective study revealed that out of 22 children of 3 months to <6 years of age with a significant rise in CF titer 19 (86 %) had a positive virus isolation. Of the 3 CF positive children who failed to yield virus, one was 3 months old and already at the convalescent phase of infection at the time of sampling, the age of the 2 others being 5 years. The findings seem to reflect increasing difficulties in isolating RS virus from children of 5 years or over and are, in this respect, in agreement with the experience of others (1, 43, 57). On the basis of the results it would appear that the efficiency of the isolation method used in the present study in detecting acute RS virus infection in children under 5 years of age is between 86 and 100 %.

To determine the diagnostic efficiency of the CF test, 22 children of from 1 month to <6 years of age with positive RS virus isolations were kept under observation for the development of a subsequent rise in titer. Nineteen developed a significant antibody response, while 3 failed to do so. The latter were 1, 3 and 11 months old respectively. The results showed a diagnostic efficiency for the CF test of 86 % for all children (similar to that of the isolation method) and of 100 % for those of 1 year or over. The isolation method was thus highly efficient in detecting infection in subjects under 5 years, and the CF test in subjects of 1 year or over.

had only 1 throat swab been taken from each child shortly after hospitalization for the inoculation of only 1 tissue culture tube.

In the first study (I) virus isolation specimens were obtained *from 76 children*, all of whom had acute respiratory illness. RS virus was isolated from 7 out of 11 (64 %) subjects with bronchiolitis, 7 *out of 14 (50 %)* with pneumonia 6 out of 28 (21 %) with bronchitis and 3 out of 23 (13 %) with infection of the upper respiratory tract. Similar results have been obtained by other investigators (9 15) all indicating the association of severe respiratory disease with RS virus infection. It can be noted that the association rate was highest for the bronchiolitis syndrome, which is again in agreement with the findings of others (9 15 17). The rate of positive isolations decreased with age as also shown previously (9 15 47). A noticeable feature was that the agent was recovered from no less than 5 out of 7 (70 %) of the infants under 3 months of age, suggesting its importance as a cause of infection in the first stages of life (I).

The documented low titered and slow antibody response of very young infants to RS virus infection was also investigated to some degree in the present study (I II). In the first study (I) none of the < 3 month-old subjects showed significant (4-fold or greater) rises in CF titer for RS virus, although an RS virus isolation was obtained from some of them. These findings are not surprising as the interval between the paired serum specimens was only 1 to 2 weeks and the serum titrations were initiated from a comparatively high (1/8) dilution. In the second study (II) which was for the *main part a* serological study the sera were collected at an identical interval but the *CF* titrations were initiated from a 1/4 dilution. Of the 25 infants of < 3 months of age tested, 3 (12 %) showed a significant CF antibody response to RS virus. However not even this number would have shown a significant rise in titer had the serum titration been initiated from a 1/8 dilution since the convalescent titers never exceeded 1/8. In contrast the convalescent titers of the children of 1 year or over always exceeded 1/8. A comparison revealed that 19 subjects out of 35 *(54 %)* in the age group 3 — < 6 months had significant titer rises, as compared with 26 out of 39 (67 %) in the age group 6 — < 12 months and 11 out of 20 (55 %) in the age group 12 — < 24 months. The actual rate of RS virus infection among those of < 3 months of age remained unknown as virus isolation specimens were not taken, but was probably higher than the 12 % observed. The fact that no less than 8 of the < 3 month-old infants developed a weak rise in titer from < 1/4 to 1/4 or from 1/4 to 1/8 speaks in favor of this assumption. On the basis of the results it could be concluded that convalescent serum specimens should not be obtained from infants of < 3 months of age, before the 5th week of illness, and that titration of their RS virus CF antibody should preferably be initiated from a serum dilution of 1/4 or lower.

In a study of the family members of children with RS virus infection (IX) 7 parents were shown to develop significant CF antibody titer rises to the agent of from < 1/4 to 1/8 or from < 1/4 to 1/16. With the reservation that

fection occurred in the nursery (III) each coinciding in time with the RS virus epidemics in the city and involving a minimum of 58 % and 83 % of the occupants respectively. During an RS virus epidemic in the city of Helsinki extending from December 1963 to about February 1964 (II) infants in 3 residential nurseries were sampled in order to discover whether they possibly had RS virus infection; the occupants in both localities were found to be heavily infected with the agent. The importance of the RS virus as a cause of respiratory disease among nursery groups of children was subsequently further evaluated in another study (VIII). Of the subjects hospitalized for disease due to the agent, 44 % were day nursery children whereas among those hospitalized during the same time for infections due to respiratory pathogens other than RS virus, the proportion of children in this category was only 8 % ($p < 0.01$).

Another of the epidemiological characteristics of the RS virus infection seemed to be its tendency to occur in families (IX). The agent was a common cause of infection among the members of 25 families, leaving 23 other control families, with one exception, unaffected. Of the members of the RS virus infection-positive families, the adult subjects showed rising titers, whereas the children showed either rising titers or titers which had already reached a high level. On the basis of these results it was suggested that RS virus was not brought into the family by the adult members (the parents) but by some of the children.

In Table 1 3 strains of RS virus are compared with a fourth one. The Randall strain, isolated by Beem *et al.* in the U.S.A. in December 1958 (9). As can be seen, the Anderson strain showed antigenic similarities to the Randall strain, unlike the two other strains.

Discussion

The RS virus epidemics recorded in the city of Turku were roughly of 8

EPIDEMIOLOGY (I, II, III, VIII, IX, XI)

Methods

Continuous surveillance was maintained during the period September 1963 to December 1966 on the incidence of RS virus infection among the pediatric population of the city of Turku. This surveillance consisted predominantly of a search for RS virus in throat swabs and rising CF antibody titers to the agent in paired serum specimens delivered from the Hospital for Infectious Diseases in the city Comparison of the antigenic properties of RS virus strains from different epidemics was carried out according to a neutralization technique described in study No X. The test was read after 4 days.

Results

Four fairly sharply limited outbreaks of RS virus infection occurred in the city The first one extended from November 1963 to January 1964 the second from April to June, 1965 the third from September to November 1965 and the fourth from October to December 1966 In the inter-epidemic periods there were no positive RS virus isolations or serological evidence of infection with the agent. Each of the epidemics were approximately of 2½ to 3 months duration The localization of the epidemics in time indicates that RS virus was prevalent in the community each year but at irregular intervals varying from 3 months to 1 year and 2 months.

Studies on children under 6 years of age admitted to the Hospital for Infectious Diseases during 2 month study periods throughout the duration of the first and second RS virus epidemics revealed that the RS virus infections were on each occasion differently distributed according to age In the course of the first outbreak (I) the total number of children admitted for acute respiratory disease was 87 of whom 30 % were suffering from RS virus infection. Infections with the agent were particularly common in the youngest age groups, with the highest frequency (75 %) occurring among infants under 3 months of age the infection rate being only 9 % in the 2 to <6 year-old group During the second outbreak (VIII) a total of 60 subjects were admitted of whom not less than 57 % had RS virus infection. RS virus infection was on this occasion most frequent in the age group 3 to <6 months (infection rate 100 %) but was also common among older children, the 2—<6 year-old group showing an infection rate of not less than 55 %

Surveillance was maintained from September 1963 to June, 1965 on the incidence and spread of RS virus infection in a residential nursery in the city intended for infants under 2 years of age. Two outbreaks of RS virus in

fection occurred in the nursery (III) each coinciding in time with the RS virus epidemics in the city and involving a minimum of 58 % and 83 % of the occupants respectively. During an RS virus epidemic in the city of Helsinki extending from December 1963 to about February 1964 (II) infants in 2 residential nurseries were sampled in order to discover whether they possibly had RS virus infection; the occupants in both localities were found to be heavily infected with the agent. The importance of the RS virus as a cause of respiratory disease among nursery groups of children was subsequently further evaluated in another study (VIII). Of the subjects hospitalized for diseases due to the agent, 44 % were day-nursery children, whereas among those hospitalized during the same time for infections due to respiratory pathogens other than RS virus, the proportion of children in this category was only 8 % ($p < 0.01$).

Another of the epidemiological characteristics of the RS virus infection seemed to be its tendency to occur in families (IX). The agent was a common cause of infection among the members of 25 families, leaving 23 other control families, with one exception, unaffected. Of the members of the RS virus infection-positive families, the adult subjects showed rising titers, whereas the children showed either rising titers or titers which had already reached a high level. On the basis of these results it was suggested that RS virus was not brought into the family by the adult members (the parents) but by some of the children.

In Table 1 3 strains of RS virus are compared with a fourth one. The Randall strain, isolated by Beem et al. in the U.S.A. in December 1958 (9). As can be seen, the Anderson strain showed antigenic similarities to the Randall strain, unlike the two other strains.

Discussion

The RS virus epidemics recorded in the city of Turku were roughly of 3

months duration and recurred at on the average, yearly intervals during the fall winter or spring. In one case the prevalence of infection extended until late June. The findings regarding the seasonal and yearly occurrence of RS virus infection are in conformity with observations from other parts of the world.

Cross neutralization tests were not performed in the present study so there is no information about the reciprocal antigenic relationship between the different epidemic strains isolated. However some of the strains were compared with each other in respect of their ability to be neutralized by Randall virus antiserum. By this means it was indirectly shown that the strains from two subsequent epidemics, that of fall 1963 and spring 1965 were antigenically distinct from each other

It can be assumed that there were high numbers of infants susceptible to RS virus at the time of the onset of the spring 1965 outbreak, since as far as is known the agent had not been prevalent in the community at all during the preceding 1 year and 3 months. Accordingly there was reason to expect a widespread dissemination of infection on this basis. As a matter of fact however certain findings seem to indicate that the spread of infection was not so extensive as expected. One is the observation that the number of admissions of very young infants with RS virus infection was comparatively small The consequences of the late onset of the outbreak in April cannot be surveyed but it appears probable that the conditions for efficient virus dissemination were not optimal at that time, and still more unfavourable during the later course of the outbreak in May and June. In view of all this, it seem possible — although direct evidence lacking — that the agent remained a tive to a limited extent somewhere the community during July and Augu until reinvolved in the well-defined ou break extending from the middle of Se tember to late November of the sam year This seems to be more plausible the inter-epidemic period was actual only about 2½ months, and the 2 strai isolated during each of the epidemi were both antigenically distinct from th Randall strain in a similar way Un fortunately both strains were not com pared directly with each other in ord to demonstrate the presence of reciproc antigenic similarities.

It was noticed that during the R virus epidemics, the agent frequently in vaded nurseries causing a high rate o infection among the occupants, and tha there was a high proportion of day nursery children among the ones who had to be hospitalized for RS virus in fection Although the reservation must be made that the social reasons for hospitalization were possibly more pressing for day nursery children than for chil dren in other categories, it would seem that RS virus infection is frequent among nursery populations. As there is, for the present a highly increasing need for more day nurseries in many urban communities due to the considerable num bers of mothers working outside the home it would seem that the importance of the agent as a cause of respiratory disease in nursery groups of children may increase further

The present study presented presumptive evidence that RS virus infection is transmitted into a family probably not

by the adult members but by the children. Moreover the results indicated a high rate of RS virus infection among the members of some families and, on the other hand, absence of infection with the agent in other families. The findings raise the question of whether there was any close association between infection in the family and infection in the nurseries, particularly the open nurseries taking care of the children during the day and sending them home in the evening. The possibility of such an association would imply the transmission of respiratory pathogens from inside the nursery to the family household unit. At present, as far as is known, there is not much knowledge about the relative importance of this means in the spread of RS virus infection.

CLINICAL FEATURES (I, II, VIII)

Material and methods

The material consisted of a total of 120 children hospitalized for acute respiratory disease associated with RS virus infection by virus isolation and/or a significant rise in CF antibody titer. Twenty-seven of the subjects were hospitalized in Turku in December 1963 and January 1964 (I), 59 during the same period in Helsinki (II) and 34 in May and June 1965 in Turku (VIII). Rhinitis and/or cough were taken to indicate an upper respiratory infection; additional rhonchi, wheezing or musical râles indicated bronchitis. Signs of breathing difficulties due to obstruction such as prolonged expiration, retraction, cyanosis and tachypnea indicated bronchiolitis; crepitant rales and/or apparen x ray evidence of infiltration of the lun parenchyma indicated pneumonia.

Results

Table 2 assembles data on all the 12 RS virus-infected children giving an indication of the relation of age to clinica syndrome. Bronchiolitis, as it was defined in the present study, was a charac teristic feature among infants of les than 1 year but was highly infrequent in the older age groups. In contras pneumonia was common up to the age of 2 years, but also occurred in the 2—<6 year-old group. As can be seen, the rate of severe lower respiratory dis-

Virus isolation from throat swabs, and/or 4 fold or greater rise in CF antibody titer.
Pneumonia, bronchiolitis with pneumonia, or bronchiolitis.

case was highest in the under 3 month-old group (90 %) and showed a definite decrease with age. No fatalities occurred.

The duration of the respiratory illness and fever was approximately equal for groups of infants with RS virus infection, one (I) of which consisted of subjects < 1 year and the other (II) of subjects < years of age. The children had been ill for an average of 4 days prior to admission (II) and their illness varied in length from 7 to 21 days, being, on average, 14 (I) and 13 (II) days. The fever (higher than 37.5°C per rectum) lasted 4 days (I) or — as measured in the ward — 3 days (II) on average. The maximal duration of fever was 7 days (II). The temperature of the patients under 6 months of age never exceeded 38.1 but the temperature of those of 6 to < 12 months of age always exceeded 38.4 C per rectum (I). The percentage rates of the more severe respiratory symptoms were as follows: Dyspnoea 77 (I) and 86 (II); cyanosis 23 (I) and 22 (II); wheezing 65 (I) and 34 (II); crepitant râles 77 (I); retraction 68 (I).

Discussion

There is a striking correspondence between the present results and those achieved by McClelland *et al.* (44) in an investigation of 109 children with RS virus infection. Both studies demonstrate the high frequency with which RS virus bronchiolitis occurs in infants up to the age of 1 year and the infrequency of this clinical syndrome among children of 1 year or over. In the present series the rate of bronchiolitis and bronchiolitis with pneumonia was not less than 41 % in the under 1 year-old group but only 5 % in the 1—<2 year-old group, being 0 % in the older age groups. In contrast to the bronchiolitis syndrome, pneumonia was comparatively common up to the age of 2 years and over. This observation also corresponds to the findings of McClelland *et al.* (44).

Although a proportion of the subjects studied were admitted for social and otological (otitis media) reasons, the majority were considered to be in need of hospital care for their severe lower respiratory disease and were hospitalized on these grounds. The present material of 120 children thus represents, to a considerable extent, a selection of the severest cases of RS virus infection. It can be emphasized that the results hence do not give any direct indication of the rate of severe lower respiratory disease caused by the agent among the open pediatric population of the city.

CLINICAL FEATURES (I, II, VIII)

Material and methods

The material consisted of a total of 120 children hospitalized for acute respiratory disease associated with RS virus infection by virus isolation and/or a significant rise in CF antibody titer Twenty-seven of the subjects were hospitalized in Turku in December 1963 and January 1964 (I) 59 during the same period in Helsinki (II) and 34 in May and June 1965 in Turku (VIII) Rhinitis and/or cough were taken to indicate an upper respiratory infection additional rhonchi wheezing or musical râles indicated bronchitis. Signs of breathing difficulties due to obstruction such as prolonged expiration retraction cyanosis and tachypnea indicated bronchiolitis crepitant rales and/or apparent x ray evidence of infiltration of the lung parenchyma indicated pneumonia.

Results

Table 2 assembles data on all the 120 RS virus-infected children giving an indication of the relation of age to clinical syndrome. Bronchiolitis, as it was defined in the present study was a characteristic feature among infants of less than 1 year but was highly infrequent in the older age groups. In contrast pneumonia was common up to the age of 2 years, but also occurred in the 2—<6 year-old group As can be seen the rate of severe lower respiratory dis-

TABLE 3. *Rate of respiratory syncytial (RS) virus isolations from middle ear aspirates of 28 children with RS virus infection*

Epidemic	No. children yielding virus from one or both ears / No. children punctured	No. ears yielding virus / No. ears punctured
Spring 1963	9/10 (90 %)	13/17 (76 %)
Fall 1963	7/18 (39 %)	11/34 (32 %)
Total	16/28 (57 %)	24/51 (47 %)

RS virus isolation from throat swabs.

containing exudates were sometimes thin and sanguinous.

Virus was recovered during the fall study with about equal frequency from ears with injected, reddened and/or bulging eardrums (isolation rate 30 %) and ears lacking these signs of inflammation (isolation rate 35 %). One child whose eardrums were reddened and dull and who did not receive treatment with antibiotics at the time of the puncture yielded RS virus and *Haemophilus influenzae* from both ears (XI).

The aspirates which yielded virus were obtained from the 3rd to 9th day after the onset of the respiratory symptoms (IV, V, XI). Only 1 of the aspirates obtained at repuncture contained virus. In this case the time interval between the two positive exudate specimens was 4 days (XI). Only 1 of the children studied was with certainty known to be suffering from RS virus reinfection. The aspirates of this boy obtained 7 days after the onset of respiratory symptoms were negative for virus (XI).

As previously indicated (IV), cultures were simultaneously inoculated with throat swabs and aspirate specimens. The time required for the CPE to become apparent varied greatly but was in general shorter for the swab-inoculated cultures than for the cultures inoculated with aspirates. It never occurred that RS virus was recovered from middle ear aspirates, but not recovered from the throat swabs taken at the same time from the same subject. On the contrary it often happened that the aspirates were negative, but the throat swabs yielded virus, especially in the later course of the disease.

Discussion

Although it is not known whether RS virus is capable of multiplying in the human middle ear epithelium, the accumulation of RS virus-containing mucus in the tympanum seems to justify the use of the term *RS virus otitis*. The affection can be detected by a careful examination of the eardrums. The spring study (IV, V) convincingly demonstrated its clinically weak manifestations. None of the 9 infants suffering from RS virus otitis developed any signs of more

OTOLOGY (IV, V, VI)

Material and methods

The patients were young children who were admitted to the wards of the Children's Clinic of the University or the Hospital for Infectious Diseases in Helsinki, or were seen in the outpatient department of the Otolaryngological Clinic of the University. All patients took part in the study during the RS virus outbreaks in spring 1965 (IV, V) and fall 1965 (VI). RS virus was isolated from the throat swabs of a total of 28 children. The ages of these 28 subjects who were suffering from RS virus infection and who will be considered otologically in greater detail in this report were as follows:

Epidemic	Age in months	Inpatients	Outpatients
Spring 1965	12	9	
	21		1
Fall 1965	<12	16	
	12	1	
	38		1
	Total	26	2

Middle ear exudate specimens were obtained with a syringe and needle by a puncture aspiration technique and the aspirates withdrawn were immediately inoculated undiluted through the needle into a HeLa cell culture tube. The ear drums of each child were punctured once or more times during the course of the respiratory illness. Because only the first later results than the first punctures will be discussed and recorded in the tables. Not less than 18 (64%) of the 28 subjects were treated with antibiotics at the time of the puncture.

Results

RS virus was isolated from the middle ear aspirates of 16 (57%) of the children or from 21 (75%) of the ears punctured. However, as shown in Table 1 the isolation rate varied from time to time, being higher in the spring than in the fall. Of the 10 children in the spring series, 9 (all of whom were ≤12 months old) had isolation positive and 1 (21 months old) isolation negative aspirates. Of the 18 children of the fall series only 7 (6 of whom were ≤12 and one 38 months old) had isolation positive aspirates.

All children included in the spring study (IV, V) displayed signs of a very weak middle ear affection. The eardrum was pale, dull or lustreless, thin or slightly thick and in normal position, the light and with the reflex visible or invisible. The RS virus containing exudates obtained from these cases were clear and mucous and did not contain pathogenic bacteria. In contrast, a considerable proportion of the children in the fall study (VI) displayed signs of a more acute middle ear inflammation. Their virus

Results

RS virus was isolated from the middle ear aspirates of 16 (57 %) of the children or from 24 (47 %) of the ears punctured However as shown in Table 3, the isolation rates varied from time to time, being higher in the spring than in the fall Of the 10 children in the spring series, 9 (all of whom were ≦12 months old) had isolation positive and 1 (21 months old) isolation negative aspirates. Of the 18 children of the fall series, only 7 (5 of whom were <12 one 22 and one 38 months old) had isolation positive aspirates.

All children included in the spring study (IV V) displayed signs of a very weak middle ear affection The eardrum was pale, dull or lustrous, thin or slightly thickened in normal position, rigid and with the reflex visible or invisible. The RS virus-containing exudates obtained from these ears were clear and mucous or serous, and did not contain pathogenic bacteria. In contrast a considerable proportion of the children in the fall study (XI) displayed signs of a more severe middle ear inflammation their virus-

cumulation and a rigid eardrum in young infants with narrow external acoustic meatus. The advantages of the puncture aspiration technique and the direct inoculation technique used in the present study can not be evaluated in greater detail since alternative methods were not employed.

severe inflammation such as redness or injection of the eardrum. As a matter of fact only rigidity of the drum was common to all of the children as revealed by the use of Siegle's pneumatic speculum and probably mainly attributable to intratympanic mucus accumulation. The fact that RS virus otitis may heal without the development of more pronounced signs of inflammation seems to indicate that the affection is comparatively harmless and probably without clinical significance provided the occurrence of complicating bacterial otitis media can be avoided

If uncomplicated RS virus otitis were associated with redness, injection or bulging of the drums, one would expect to find these signs regularly in infants infected with the agent This, however is not the case Out of 13 infants suffering from RS virus pneumonia in a nursery in the U.S.A., 7 (50 %) had reddened tympanic membranes (39) but among 15 RS virus-infected infants in another nursery in Stockholm Sweden there was no evidence at all of this feature (56) According to other reports, *RS virus infection may be associated* with definite signs of otitis media in 8 to 32 % of the cases (35 46 49 58) It would seem that the variations in the occurrence of eardrum signs in association with respiratory illness due to RS virus, can only be explained on the basis of variations in the rates of complicating bacterial middle ear inflammation It seems clear that the risk of an extensive spread of bacterial respiratory pathogens is increased during RS virus outbreaks, particularly in institutions providing care for infants, and that concomitant bacterial middle ear infection may thus be a common occurrence in a number of young RS virus-infected children, if not prevented by prophylactic treatment with antibiotics or other measures. It is not known to what extent and by what mechanism RS virus otitis lowers the resistance of the middle ear to superinfection but it is possible that the presumptive destruction of the epithelium may help bacterial pathogens to penetrate it and invade the submucosal space It appears likely that lack of aeration and drainage may be one, if not the most important factor contributing to the aggravation of the symptoms of bacterial inflammation.

Successful isolation of RS virus from the middle ear is facilitated by early puncture. On no occasion was the agent recovered later than the 9th day after the onset of the respiratory disease. Under favourable conditions the agent can be recovered from the ears of 100 % of the infants of 12 months or younger (IV V) Only a few older children were sampled so there is no data available on the chances of a positive isolation from the aspirates of subjects of over 1 year of age. The results indicate simply that virus-positive aspirates can be obtained up to the age of at least 3 years (XI) It is worthy of note that exudates from ears with simultaneous bacterial middle ear inflammation were also capable of yielding virus. It was desirable or important to change the inoculated cultures to fresh medium as soon as possible after the virus adsorption in order to diminish the occasionally toxic effect of the exudate on the cell culture A useful requisite was a new model of Siegle's pneumatic speculum specially designed to demonstrate intratympanic mucus ac-

cumulation and a rigid eardrum in young infants with narrow external acoustic meatus. The advantages of the puncture aspiration technique and the direct inoculation technique used in the present study can not be evaluated in greater detail, since alternative methods were not employed.

severe inflammation such as redness or injection of the eardrum. As a matter of fact only rigidity of the drum was common to all of the children as revealed by the use of Siegle's pneumatic speculum and probably mainly attributable to intratympanic mucus accumulation. The fact that RS virus otitis may heal without the development of more pronounced signs of inflammation seems to indicate that the affection is comparatively harmless and probably without clinical significance provided the occurrence of complicating baterial otitis media can be avoided.

If uncomplicated RS virus otitis were associated with redness, injection or bulging of the drums, one would expect to find these signs regularly in infants infected with the agent. This, however is not the case. Out of 13 infants suffering from RS virus pneumonia in a nursery in the U.S.A. 7 (50 %) had reddened tympanic membranes (39) but among 15 RS virus-infected infants in another nursery in Stockholm, Sweden there was no evidence at all of this feature (56). According to other reports RS virus infection may be associated with definite signs of otitis media in 8 to 32 % of the cases (35 46 49 58). It would seem that the variations in the occurrence of eardrum signs in association with respiratory illness due to RS virus, can only be explained on the basis of variations in the rates of complicating bacterial middle ear inflammation. It seems clear that the risk of an extensive spread of bacterial respiratory pathogens is increased during RS virus outbreaks, particularly in institutions providing care for infants, and that concomitant bacterial middle ear infection may thus be a common occurrence in a number of young RS virus-infected children if not prevented by prophylactic treatment with antibiotics or other measures. It is not known to what extent and by what mechanism RS virus otitis lowers the resistance of the middle ear to superinfection but it is possible that the presumptive destruction of the epithelium may help bacterial pathogens to penetrate it and invade the submucosal space. It appears likely that lack of aeration and drainage may be one if not the most important factor contributing to the aggravation of the symptoms of bacterial inflammation.

Successful isolation of RS virus from the middle ear is facilitated by early puncture. On no occasion was the agent recovered later than the 9th day after the onset of the respiratory disease. Under favourable conditions the agent can be recovered from the ears of 100 % of the infants of 12 months or younger (IV V). Only a few older children were sampled so there is no data available on the chances of a positive isolation from the aspirates of subjects of over 1 year of age. The results indicate simply that virus-positive aspirates can be obtained up to the age of at least 3 years (XI). It is worthy of note that exudates from ears with simultaneous bacterial middle ear inflammation were also capable of yielding virus. It was desirable or important to change the inoculated cultures to fresh medium as soon as possible after the virus adsorption, in order to diminish the occasionally toxic effect of the exudate on the cell culture. A useful requisite was a new model of Siegle's pneumatic speculum specially designed to demonstrate intratympanic mucus ac-

EXPERIMENTAL (VI, VII, X)

Material and methods

The study of the susceptibility of the middle ear of the guinea pig to RS virus (VI VII) included 6 experiments in which the ears of a total of 34 animals were inoculated with virus, and the ears of 7 animals with control fluid from uninoculated tissue cultures. Two strains of virus were used The Randall and the Lamminpää strains. The latter strain had been isolated in the spring 1965 from a middle ear aspirate of a child with RS virus otitis. The inoculation technique was as follows About 0 1 ml virus suspension or control fluid was injected through the eardrum using a needle and syringe. The animals were killed after 5 7 or 14 days the middle ear cleft entered through the temporal bone and specimens obtained from the middle ear for the isolation of virus and bacteria. The virus isolation specimens were obtained either with a platinum loop by removing small pieces of the mucosa or by washing the cleft After sampling the temporal bone with its accompanying middle ear was removed for histological examinations. A considerable number of the animals suffered from natural chronic bacterial otitis media

In the study of the immune response of guinea pigs to intranasal and intracardiac RS virus inoculations (X) 8 guinea pigs were inoculated with virus (Strain Randall) and 3 with control fluids from uninoculated tissue cultures. The virus used for intranasal instillations was grown in U cells, and the virus used for intracardiac injections in primary guinea pig kidney tissue cultures. Serum specimens were examined for neutralizing and CF antibody and for precipitating antibody using an agar gel diffusion technique.

Results

Virus was isolated from the middle ear cavity of the animals 5 and 7 days post inoculation (VI VII) all the specimens obtained 14 days post inoculation were negative for virus. The washing method was superior to the one in which the virus was isolated from mucosal pieces. With the washing method the agent was recovered from 25 % of the isolation specimens obtained but with the latter method from only 7 %. The agent was recovered proportionally more frequently in ears free from bacterial inflammation than from ears naturally infected with bacteria. With the washing technique RS virus was isolated from 47 % of the ears in the former category but from only 13 % of the ears in the latter category Similar isolation rates were noticed for the both virus strains used in the experiments.

Histological examination of the ears with no bacterial inflammation yielded

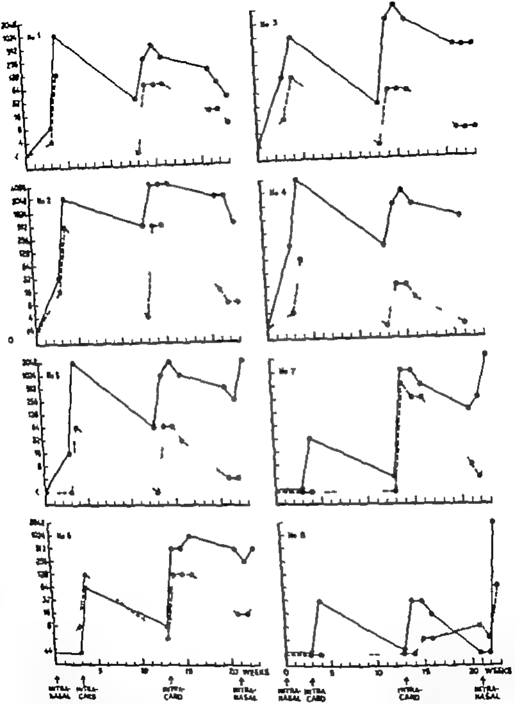

Fig. 1 — Antibody response of guinea pigs to intranasal and intracardiac inoculations of respiratory syncytial virus. Inoculations are indicated by arrows. Points connected by solid lines indicate neutralizing antibody titers; points connected by dotted lines, complement fixing antibody titers.

the following results (VI VII) A weak inflammation of subacute type was noticed in 77 % of the virus inoculated ears from which virus was recovered in 70 % of the virus-inoculated ears from which virus was not recovered and in none of the ears (only 8 in number) inoculated with control fluid The subacute inflammation typical of the virus-inoculated ears was characterized by edema proliferation of the connective tissue and infiltration predominantly with lymphocytes, histiocytes and macrophages. In 3 ears, multinucleated giant cells were seen in the exudate on the surface of the epithelial lining of the bulla. Out of 26 animals none showed antibody 5 or 7 days after the virus inoculation but on the 14th day a low level RS virus antibody response was noticed in 2 animals out of 8

The immune response of the guinea pig to RS virus inoculations was evaluated in greater detail in study No X. Figure 1 shows the neutralizing and CF antibody responses of the 8 guinea pigs receiving intranasal and intracardiac inoculations of virus. As can be seen, the extent of antibody formation after the 2 intranasal inoculations varied greatly the 2 intracardiac inoculations were followed by a more uniform antibody formation. None of the virus-inoculated or 3 control animals showed CF antibody against the antigens present in the U cell cultures none of the control animals developed antibody against RS virus.

A maximum of 3 different virus-specific precipitation lines were detected (X) The lines were marked *a*, *b* and *c*. The *a* line was situated nearest to the antigen well. The *b* line was mostly situated half way between the antigen and the serum well, and it was often duplicated. The *c* line was always ad

herent to the serum well. All of the serum specimens of the virus-inoculated guinea pigs, except one, were negative for specific precipitating antibody when tested with control antigen, as were also all sera from the control guinea pigs when tested with viral antigen. Table 4 shows the temporal occurrence of precipitating antibody in the 8 guinea pigs receiving inoculations of virus.

Discussion

The question of whether the RS virus was reproducing or was being simply mechanically preserved in the middle ear of the guinea pigs could not be solved conclusively in the present study since tissue homogenates of the mucosa were not prepared, and no titrations carried out to demonstrate a rise in the infectivity titer of the agent in this tissue, nor were other methods used to directly demonstrate the presence of the agent in the mucosal cells of the middle ear. However, the study provided indirect presumptive evidence that virus reproduction was taking place in the middle ear of the animals: 1) The agent was recovered 7 days post inoculation from the ears of a considerable number of the animals. Since RS virus loses its infectivity comparatively rapidly at temperatures around those of the guinea pig middle ear, it is not likely that it would have lived through the period from inoculation to sampling without reproducing. 2) The inflammatory reaction of the ears inoculated with virus as compared to the apparently normal histological picture of the ears which were inoculated with control fluid. 3) The presence of multinucleated giant cells probably of epithelial origin in the exudate on the epithelial lining of some of the virus-inoculated ears.

Two advantages of the method of preparing hyperimmune guinea pig RS virus antiserum by giving the animals a combination of 1 intranasal and 2 intracardiac inoculations, were the high titered specific neutralizing, CF and precipitating antibody formation even after the first booster and the absence of host (tissue culture) antibody response. It was necessary to give 2 boosters, since the precipitin response was more complete after the second one than after the first.

the following results (VI VII) A weak inflammation of subacute type was noticed in 77 % of the virus-inoculated ears from which virus was recovered, in 70 % of the virus-inoculated ears from which virus was not recovered and in none of the ears (only 8 in number) inoculated with control fluid The subacute inflammation typical of the virus-inoculated ears was characterized by edema, proliferation of the connective tissue and infiltration predominantly with lymphocytes, histiocytes and macrophages. Discussion

The question of whether the RS virus was reproducing or was being simply mechanically preserved in the middle ear of the guinea pigs could not be solved conclusiv ly in the present study since tissue homogenates of the mucosa were not prepared, and no titrations carried out to demonstrate a rise in the infectivity tit r of the agent in this tissue nor were other methods used to directly demonstrat the presence of the agent in the mucosal cells of the middle ear However the study provided indirect presumpti evidence that virus reproduction was taking place in the middle ar of the animals. 1) The agent was recovered 7 days post inoculation from the ears of a considerable number of the animals. Since RS virus loses its infectivity comparatively rapidly at temperatures around those of the guinea pig middle ear it is not likely that it would have lived through the period from inoculation to sampling without reproducing. 2) The inflammatory reaction of the ears inoculated with virus as compared to the apparently normal histological picture of the ears which were inoculated with control fluid. 3) The presence of multinucleated giant cells probably of epithelial origin in the exudate on the epithelial lining of some of the virus-inoculated ears.

Two advantages of the method of preparing hyperimmune guinea pig RS virus antiserum by giving the animals a combination of 1 intranasal and 2 intracardiac inoculations, were the high tit red specific neutralizing CF and precipitating antibody formation even after the first booster and the absence of host (tissue culture) antibody response. It was necessary to give 2 boosters, since the precipitin response was more complete after the second one than after the first.

SUMMARY

1. The method of inoculating sensitive tissue cultures directly with applicators containing throat secretions proved useful for the isolation of RS virus. A continuous line of human amnion (U cells) proved more suitable than the BS-C1 cells. The mean time required for the CPE to become apparent was 6 days for the former type of culture and 13 days for the latter. Eighty % of the positive U cultures showed a definite CPE within 1 week following inoculation. The likelihood of detecting RS virus infection in children under 6 years of age by the direct inoculation technique using U cells was higher during the first week of illness (82 % positive specimens) than in the second (49 % positive specimens), third (21 % positive specimens) and fourth weeks (11 % positive specimens). Two throat swabs, each immersed in a separate tissue culture tube, proved sufficient for the isolation of the virus at the acute stage, but during the later course of the disease it was desirable to inoculate more than 2 tubes. RS virus was isolated from 64 % of children with bronchiolitis, 60 % with pneumonia, 21 % with bronchitis and 13 % with upper respiratory infection. The proportion of children positive by isolation decreased with age. Not less than 70 % of the under 3 month-old subjects with respiratory infection yielded the agent. In order to improve the chances of a positive serodiagnosis by the CF technique in children under 3 months of age it was found necessary to initiate the titration from a serum dilution of 1/4 or lower and to employ a convalescent serum which was not obtained before the 5th week of illness. Seven adults with RS virus infection did not develop CF titers of higher than 1/16. Findings suggested that besides age previous experience with RS virus may also be a factor determining the concentration of viral antigen required in the CF test. A comparison of the isolation method (using the direct inoculation technique and U cells) and the CF test revealed the following results. The isolation method was highly efficient in detecting infection in subjects under 5 years (efficiency 86—100 %), the CF test in subjects of 1 year or over (efficiency 100 %).

2. Four fairly sharply limited outbreaks of RS virus infection, each of about 3 months duration, occurred in the city of Turku during the period September 1963 to December 1966. The inter-epidemic periods varied in length from 3 months to 1 year and 2 months. The virus strain involved in the fall 1963 outbreak was found to be antigenically distinct from the one involved in the next outbreak in the spring 1965. During these two outbreaks there was a different distribution according to the age of the children who had to be hospitalized for RS virus infection. The

fall, 1963 series was made up of proportionally many very young infants, the spring, 1965 series of a greater proportion of older children. In one of the series (spring, 1965) the proportion of day nursery children among those having RS virus infection was not less than 44 Two outbreaks of RS virus infection in a residential nursery coincided with epidemics involving the whole city The agent also invaded nurseries in the city of Helsinki during an epidemic occurring there. RS virus infection was found to spread easily among family members, particularly among children but also to some degree among parents. Serological data suggested that the infection was brought into the families by the children.

3. A hundred and twenty children hospitalized for RS virus infection were divided into different disease categories according to age Bronchiolitis was a characteristic feature of the under 1 year old infants, but was highly infrequent among those of 1 year or over In contrast pneumonia was common up to the age of [illegible] years, but also occurred, to some degree among those of [illegible] years or over The rate of severe lower respiratory disease was highest in the under 3 month old group (90 [illegible]) and showed a decrease with age

4 Middle ear exudate specimens were obtained by puncture aspiration through the eardrum and the aspirates withdrawn immediately inoculated undiluted into [illegible] cell cultures RS virus was isolated from the throat swabs of 38 children and a positive virus isolation obtained from the aspirates of 16 (37 %) of these subjects or from 4 (47 %) of the ears punctured A higher proportion of RS virus-infected children yielded RS virus from their ears during the spring, 1965 (90 %) than during the fall 1965 outbreak (30 %) The majority of the children punctured and yielding virus were under 12 months. The oldest subject from whom a positive isolation was obtained from an aspirate was 38 months, and the youngest [illegible] months. In a considerable proportion of the cases, RS virus otitis appeared and healed without the development of redness, injection or bulging of the drum, but in other cases these signs were apparent. Since almost all the subjects were treated with antibiotics, specimens for the isolation of bacteria were not systematically obtained. One ear yielded virus twice at an interval of 4 days. The aspirates of 1 child with reddened eardrums contained both *Haemophilus influenzae* and RS virus. This child was not being treated with antibiotics. In a case of proved reinfection the aspirates were negative for virus. The agent was never isolated later than the 9th day after the onset of respiratory symptoms, although the throat swabs yielded virus continually

5. *Thirty four guinea pigs were inoculated with RS* virus via the eardrum, and 7 with control fluid. A proportion of the animals suffered from natural chronic bacterial otitis media. The agent was isolated from the middle ear cavity 3 and 7 days post inoculation. About 4 times as many positive isolations were obtained by washing the middle ear as by another method in which the isolation specimens consisted of mucosal pieces. The agent was recovered 1 week after inoculation from 4[illegible] % of the ears free from bacterial inflammation, but from only 13 % of the ears naturally infected

SUMMARY

1. The method of inoculating sensitive tissue cultures directly with applicators containing throat secretions proved useful for the isolation of RS virus. A continuous line of human amnion (U cells) proved more suitable than the BS-C1 cells. The mean time required for the CPE to become apparent was [illegible] days for the former type of culture and 13 days for the latter. Eighty % of the positive U cultures showed a definite CPE within 1 week following inoculation. The likelihood of detecting RS virus infection in children under 6 years of age by the direct inoculation technique using U cells was higher during the first week of illness (62 % positive specimens) than in the second (49 % positive specimens), third (21 % positive specimens) and fourth weeks (11 % positive specimens). Two throat swabs, each immersed in a separate tissue culture tube, proved sufficient for the isolation of the virus at the acute stage, but during the later course of the disease it was desirable to inoculate more than 2 tubes. RS virus was isolated from 64 % of children with bronchiolitis, 50 % with pneumonia, 21 % with bronchitis and 13 % with upper respiratory infection. The proportion of children positive by isolation decreased with age. Not less than 70 % of the under 3 month-old subjects with respiratory infection yielded the agent. In order to improve the chances of a positive serodiagnosis by the CF technique in children under 3 months of age it was found necessary to initiate the titration from a serum dilution of 1/4 or lower and to employ a convalescent serum which was not obtained before the 5th week of illness. Seven adults with RS virus infection did not develop CF titers of higher than 1/16. Findings suggested that besides age previous experience with RS virus may also be a factor determining the concentration of viral antigen required in the CF test. A comparison of the isolation method (using the direct inoculation technique and U cells) and the CF test revealed the following results: The isolation method was highly efficient in detecting infection in subjects under 5 years (efficiency 86—100 %), the CF test in subjects of 1 year or over (efficiency 100 %).

2. Four fairly sharply limited outbreaks of RS virus infection, each of about 3 months duration, occurred in the city of Turku during the period September 1963 to December 1966. The inter-epidemic periods varied in length from 3 months to 1 year and 2 months. The virus strain involved in the fall 1963 outbreak was found to be antigenically distinct from the one involved in the next outbreak in the spring 1965. During these two outbreaks there was a different distribution according to the age of the children who had to be hospitalized for RS virus infection. The

fall, 1963 series was made up of proportionally many very young infants, the spring, 1965 series of a greater proportion of older children. In one of the series (spring, 1965) the proportion of day-nursery children among those having RS virus infection was not less than 44 %. Two outbreaks of RS virus infection in a residential nursery coincided with epidemics involving the whole city. The agent also invaded nurseries in the city of Helsinki during an epidemic occurring there. RS virus infection was found to spread easily among family members, particularly among children, but also to some degree among parents. Serological data suggested that the infection was brought into the families by the children.

3. A hundred and twenty children hospitalized for RS virus infection were divided into different disease categories according to age. Bronchiolitis was a characteristic feature of the under 1 year old infants, but was highly infrequent among those of 1 year or over. In contrast, pneumonia was common up to the age of years, but also occurred, to some degree, among those of years or more. The rate of severe lower respiratory disease was highest in the under 3 month-old group (%) and showed a decrease with age.

4. Middle ear exudate specimens were obtained by puncture aspiration through the eardrum and the aspirates were drawn immediately inoculated undiluted into cell cultures. RS virus was isolated from the throat swabs of 25 children, and a positive virus isolation obtained from the aspirates of 16 (37 %) of these subjects, or from 4 (47 %) of the ears punctured. A higher proportion of RS virus-infected children yielded RS virus from their ears during the spring, 1965 (90 %) than during the fall, 1965 outbreak (30 %). The majority of the children punctured and yielding virus were under 12 months. The oldest subject from whom a positive isolation was obtained from an aspirate was 38 months, and the youngest ? months. In a considerable proportion of the cases, RS virus otitis appeared and healed without the development of redness, injection or bulging of the drum, but in other cases these signs were apparent. Since almost all the subjects were treated with antibiotics, specimens for the isolation of bacteria were not systematically obtained. One ear yielded virus twice at an interval of 4 days. The aspirates of 1 child with reddened eardrums contained both *Haemophilus influenzae* and RS virus. This child was not being treated with antibiotics. In a case of proved reinfection the aspirates were negative for virus. The agent was never isolated later than the 9th day after the onset of respiratory symptoms, although the throat swabs yielded virus continually.

5. Thirty four guinea pigs were inoculated with RS virus via the eardrum, and 7 with control fluid. A proportion of the animals suffered from natural chronic bacterial otitis media. The agent was isolated from the middle ear cavity 5 and 7 days post inoculation. About 4 times as many positive isolations were obtained by washing the middle ear as by another method in which the isolation specimens consisted of mucosal pieces. The agent was recovered 1 week after inoculation from 47 % of the ears free from bacterial inflammation but from only 13 % of the ears naturally infected

with bacteria. Histological examination of the ears with no bacterial inflammation revealed the following results A weak subacute inflammation was noticed in 77 % of the virus-inoculated ears from which virus was recovered in 70 % of the virus-inoculated ears from which virus was not recovered and in none of the ears (only 8 in number) inoculated with control fluid. Three virus-inoculated ears showed multinucleated giant cells probably of epithelial origin.

Eight guinea pigs received intranasal and intracardiac inoculations of virus, and 3 guinea pigs similar inoculations of control fluid. The specific immune responses noticed were more uniform after the intracardiac injections. In addition to the neutralizing and CF antibodies to RS virus the animals also developed specific precipitating antibodies of 3 types. To induce a complete precipitin response it was necessary to give not less than 1 intranasal and ? intracardiac inoculations.

ACKNOWLEDGEMENTS

My sincere thanks are due to my chief Professor Pekka Halonen, Med.Sc.D. Head of the Department of Virology University of Turku, who suggested the subject to me and introduced me to the field of virology and whose scientific advice, continued support and encouragement during the course of this study have been of invaluable help. I am also grateful for all the resources of his laboratory placed at my disposal.

I am greatly indebted to Professor Johan Wickstrom, Med.Sc.D. Head of the Hospital for Infectious Diseases in Turku for his helpful advice and for making the facilities of his hospital available to me.

To Associate Professor J. A. Grönroos, Med.Sc.D. Department of Medical Microbiology University of Turku, I am greatly indebted for the interest he has taken in this study and for his advice and support.

My thanks are also due to my co-workers for their skilled co-operation without which the realization of the investigation program would not have been made possible.

The study was carried out at the Department of Virology University of Turku and in part at the Hospital for Infectious Diseases in Turku, the Otolaryngological Clinic the Departments of Medical Microbiology and Pathological Anatomy and the Children's Clinic, University of Turku, and at the Epidemic and Medical Department for Children, Aurora Hospital, Helsinki. I wish to thank the personnel of those institutions for their courtesy and assistance. I wish to thank, in particular Miss Anja Pajasmaa for her assistance in the serological tests, Mrs. Leena Soini for preparing the tissue cultures, Mrs. Tuulikki Ström for collecting samples and necessary information, and Mrs. Maija Aro for her secreterial assistance.

To my wife I express my deep gratitude for her patience and assistance in proof reading and retyping the manuscripts.

My sincere thanks are due to Mrs. Aili Ryynänen M.A. Librarian of the Faculty of Medicine University of Turku, and her assistants for help in assembling the required literature.

I am grateful to Miss Ann Matheson, M.A. The English Centre, Helsinki, for checking the language of my English manuscript, and Miss Sirkko Asp M.A. for statistical assistance.

The study was financially supported by the National Research Council for Medical Sciences, the Finska Läkaresällskapet, and the Svenska Kulturfonden, to all of which I make grateful acknowledgement.

PREFACE

The late Professor Toivo Salmi, earlier my teacher and chief, began the series of neonatal cardiologic studies in Turku with which my work is connected. I remember him with sincere gratitude. His sympathetic and friendly attitude were invaluable when I started on this work in his department.

Dr Tuomas Paltonen, M.D. Professor of Pediatrics, Head of the Children's Hospital and Clinical Supervisor of the Cardiorespiratory Research Unit of Turku University and Dr Leo Hirvonen, M.D. Associate Professor of Physiology and Head of the Cardiorespiratory Research Unit suggested this subject to me. Their very wide expert knowledge of neonatal cardiology and electrocardiography was of inestimable help in my work. I am deeply indebted to both of them for this, for their inspiration and for their encouragement throughout my work.

My thanks are also due to Dr Kaarlo Hartiala, M.D. Professor of Physiology Head of the Department of Physiology of Turku University in which the Cardiorespiratory Research Unit is located.

I am very grateful to Dr Ole Wasz-Hockert, M.D. Professor of Pediatrics, Head of the Department of Pediatrics of University of Oulu, my former chief for allowing me to supplement my material in his department and for helping me in many ways.

Professor Johan Wickström, M.D. Head of the Municipal Hospital of Turku, my present chief has followed the progress of my work with great interest. I greatly appreciate this from someone with his wide understanding of cardiology.

Mr Heikki Alikoski, Phil.lic., was my advisor on the statistical aspects of the work. I am grateful to him for his interest and co-operation. Mr Erkki Hänninen, my younger brother performed all the mathemathical calculations with commendable care.

In the recordings, I received great help from the members of the staffs of the Children's Hospital of Turku University the Department of Pediatrics of University of Oulu, Abolands Sjukhus hospital and the Cardiorespiratory Research Unit of Turku University. My work would haven been much more difficult without the help that I was accorded by all of them.

Mrs Aili Ryynänen, M.A., librarian of the Medical Library of Turku University helped in the collection of the literature for which I am very grateful.

My thanks are due also to Mrs Irja Uotila, pharmaceutical chemist, for her help with typing the manuscript and compiling the tables and the references.

Miss Päivikki Ojanaru, M.A., and Mr L. A. Keyworth, M.A. (Cantab.)

INTRODUCTION

Electrocardiography has long been an important method of cardiac study. Vectorelectrocardiography or vectorcardiography (Vcg) has made a significant contribution to the application of electrocardiography. It complements the sum of knowledge obtainable on the electrical activity of the heart. Vectorcardiographic research has its own specific spheres, whereas certain other areas of the electrical activity of the heart are displayed better by ordinary electrocardiography. It is in fact customary in many cardiac research centres to make both Ecg and Vcg recordings when studying on the surface of the skin the electrical potentials generated by the heart.

The vectorcardiographic method has been little used for newborn. But as e.g. the ratio between the action potentials of the different halves of the heart is revealed better by Vcg than by ordinary Ecg, and as this ratio is particularly difficult to assess in the newborn and is of diagnostic significance, vectorcardiography could be expected to be of great value in studying the electrical activity of the heart of the newborn. Furthermore, it is sometimes difficult, in the neonatal period in particular, to diagnose partial bundle branch blocks, which also is one of the »specialities» of vectorcardiography.

The use of the vectorcardiographic method in cardiology of the newborn seems, thus, to be very well motivated. Its application to the newborn, however, raises problems which are not encountered to the same extent in older children or adults. This may be the reason why there are *so few studies dealing with the newborn*.

The rapid progress in the facilities for treating many severe conditions of congenital heart disease operatively and at earlier ages makes it essential to improve early diagnostics. To establish firm grounds for vectorcardiographic diagnosis, we must try to ascertain from a sufficiently large material what the normal findings and dispersions are for healthy newborn infants. We must also establish which recording methods are applicable for examination of the newborn. More accurate and more reliable determination of the electrical potentials of the heart should also throw further light on the normal hemodynamics of the neonatal period.

The purpose of the present study is, within the above frame of reference, to examine the potential and technique of the vectorcardiographic method in the neonatal period and to present the normal findings.

HISTORY OF VECTORCARDIOGRAPHIC RESEARCH

The observation by Einthoven in 1913 that the waves of the scalar electrocardiogram are projections on certain axes of an imaginary heart vector which illustrates the changing electrical status of the heart is the basis of both ordinary electrocardiography and vectorcardiography [51] Einthoven was not the first to record the electrical action of the heart. Waller had made graphic recordings of the electric current generated by the human heart as early as 1887 [226]

The vectorial mode of thinking evolved by Einthoven was soon applied to electrocardiographic analysis by other workers who used it to elucidate the Ecg changes of bundle branch blocks, hypertrophies and auricular flutter [136, 235] In 1920 Mann constructed vectorcardiographic loops from an ordinary Ecg and called them monocardiograms [140]

Although these earlier studies were conducted only on the frontal plane they created a basis for the theory of the electric dipole of the heart, which has since been explained by Craib [37] who introduced the term dipole and which has become one of the fundamental ideas in the study of the electrical action of the heart. It has been claimed that Einthoven's research team was already aware of spatial vector implications, although they did not postulate them. Possibly they feared that this would make the new method of investigation look too complicated [212]

Savjaloff drew attention in 1929 to the three dimensional character of the potentials generated by the heart. He noted that in recordings made on the frontal plane only the differences of potentials emerge which are parallel to the frontal plane He denoted the spatial potential difference E^{st} its projection on the frontal plane E_a and the angle which the spatial potential difference formed with the frontal plane S This gives $E_a = E^{st} \cos S$ Consequently not much can be known about the spatial differences in potential without knowing the angle S [195]

The spatiality of potentials was studied systematically by Wilson, who placed electrodes on different parts of the trunk and determined the sagittal component between the electrodes placed before and after the heart [236]

Direct recording of vectorcardiographic (Vcg) loops became possible in 1930 when Mann announced that he had already devised in 1925 an apparatus capable of direct recording of monocardiograms, as he called them [141] He used this device for studying heart function in normal and pathologic conditions and considered that the method was very suitable for diagnosis of right and left bundle branch

blocks and helpful in the study of problems such as the site and extent of myocardial and coronary lesions, the nature of fibrillation and flutter and the sites of origin of extrasystoles. In 1938 Mann devised a new electromechanical oscillograph [142]

The cathode-ray tube, introduced in the early 1930s, made it possible to perform Vcg recordings more easily and with greater sensitivity It ushered in a new phase of development in the history of vectorcardiography The cathode-ray tube was employed in Vcg recording by two research teams almost simultaneously in 1937 and practically independently of one another viz. Schellong et al. [202] and Wilson et al. [238]

In 1937 Schellong *et al.* published three studies on Vektordiagraphie for which they used the abbreviation VD [202, 203, 204] The first paper dealt with the bases of the new technique. The second described its practical application in the differential diagnosis of conduction defects, on the one hand, and innocent notches and fragmentations on the other The third paper was a discussion of the practical method and the normal findings. Schellong had already described the method a year earlier at the Wiesbaden Congress.

It is surprising how clearly investigators were able to establish even at that time the most important characteristics of a normal Vcg finding. Many observations made by Schellong's team are still valid. For instance they found the QRS loop to be at roughly the same plane which they called »die Ebene der QRS-Schleife The configuration and spatial orientation of normal QRS and T loops were presented, likewise the concordance of QRS and T loops. Examples of normal recordings were presented. The normal QRS loop was described as having the following features.

1. dass sie in einer Hauptebene verläuft, wobei der Q-Teil und der absteigende Teil von R nach vorn, der aufsteigende Teil von R und der S-Teil nach hinten zu gelegen sind,

2. dass die QRS-Schleife eine ellipsenähnliche Form hat, die zwar in manchen Fällen durch flache Ein- und Ausbuchtungen unterbrochen werden kann, welche aber nicht aus der allgemeinen Ebene herausfallen.

The authors also suggested the possibility of using limb leads in Vcg recording. However they thought that the results obtained in this way were so inconsistent that the characteristics of a normal finding could not be established.

In 1938 Schellong reported a method of direct recording stereoscopically by moving the dorsal electrode. The two pictures obtained were then viewed stereoscopically [200]

In 1937 Hollman and Hollman also used the cathode-ray tube, using a slight modification of Schellong's example for recording vector loops [99 100] They called these triograms.

Wilson spoke on the use of the cathode-ray tube for the first time in May 1937 at the American Society for Clinical Investigation, and later in the same year in collaboration with Johnston and Barker published a written paper on it [238] He employed

in it his tetrahedron system which is still in use today

Vcg findings in left and right axis deviations and in bundle branch blocks were studied a year later by Wilson and Johnston, who also reported a case with infarction of the diaphragmatic wall of the heart. The recordings were performed in the frontal plane and time integration was included by using a broken line. These authors suggested the name vector cardiogram. The curves obtained by this method are vector functions of the time and may be called vector cardiograms. [237]

An orthogonal system which differs very little from that employed by Schellong was used in 1939 by Kimura in his recordings [116] He also discussed points of a fundamental character Kimura was influenced by Schellong, whose name is mentioned in his publication.

In 1939 Schellong wrote a comprehensive study entitled Grundzüge einer klinischen Vektordiagraphie des Herzens [201] The construction of Vcgs from scalar curves and vice versa were both described, and also the technique of Vcg recording using the Siemens-Vektordiagraph. Normal findings for different positions of the heart and the most important pathologic signs were reported. But time integration was omitted since it was not possible with this apparatus to record the loop as a broken line. The most important Vcg alterations in connection with myocardial infarctions were also described.

Once a beginning had thus been made in vectorcardiography by means of the cathode-ray tube the technique was developed rapidly Very thorough and versatile work was done in the 1940s and especially in the 1950s to clarify the theory of vectorcardiography and to evolve new and more reliable recording methods, as will be related later in this review of the literature It became customary to make the recordings in three planes to give an accurate spatial representation, and the express aim in analysing the results was determination of the quantitative facts. Many new methods of analysing and presenting the results were introduced. The literature in this field has now assumed voluminous proportions.

RECORDING SYSTEMS

When the action potentials produced by the heart are recorded from the skin there are naturally an unlimited number of alternatives for placing the electrodes. In addition, the impulses received via the electrodes can be treated in different ways. The simplest method is to direct to the horizontal and vertical electrodes of the cathode-ray tube of the oscilloscope the impulses that are obtained by recording in two directions perpendicular to one another This is done e.g in the widely used cube system introduced by Grishman [81] Another possibility is to use coefficients to change the ratio between the potentials if a system otherwise gives a component which is too great or too small, as e.g. the tetrahedron system of Wilson [238]

Many endeavours have been made to develop the vectorelectrocardiographic technique to provide the fullest possible picture of the electrical activity which occurs in the cardiac muscle, without allowing the factors caused by changes in the position of the heart or those due to the different anatomy of the surrounding tissues to affect this picture to any appreciable extent. In other words, *the aim is to have the same electrical event always to cause a Vcg loop with the same configuration* even if its position changes in accordance with the changed position of the heart. The configuration of the QRSaË loop is a very important piece of information which can be obtained only by the vectorial technique. It was shown in very fine experimental form by Burch et al. [29] that this configuration is impossible to determine even approximately from scalar leads.

Much closer to the above target are the newer so-called *corrected lead systems* in which the number of electrodes is greater and in which the potentials they emit are transformed in resistance-combining network prior to amplification. Obviously *the greater the number of electrodes, the more* accurate the results will be [149]. In planning such systems several experimental set-ups have been arranged in which the heart has been replaced by an artificial heart and the impulses it generates to electrodes on the surface of the skin have been measured [28, 230]. Instead of human cadavers, homogeneous torso models and also non-homogeneous phantom more reminiscent of man have been employed [26, 27, 28, 62, 63, 67, 68]. Fluid mappers and conducting paper mannikins have also been used [148]. The heterogeneity *of* the organism as an electric conductor interferes with all electric recordings from the skin. For instance, the quantity of lung tissue and the air content between the heart and the electrode affect considerably the amplitudes to be recorded. *Inspiratory* breath holding thus decreases the mean total QRS and T voltages in adults [17]. In addition to anatomic differences, factors such as anemia and polycythemia have also been found to influence conductivity [15]. No artificial model nor human cadaver therefore, can duplicate perfectly the conditions in living being.

The sagittal component is most susceptible to errors. A factor which distorts especially this, but *also* the *other* components, is the great difference between the so-called *image surface* and the physical human surface. The concept of image surface was introduced in 1948 by Burger and van Milaan [28]. It was reviewed and its applications discussed extensively and comprehensively by Frank [62]. With the physical human surface, the greatest distortion occurs in the sagittal component because on the image surface immediately precordially there is very large swelling anteriorly to the left, and the difference from the human physical surface is therefore greatest there. This also explains why the placing of the precordial electrodes is the most critical aspect. In other words, inaccuracy in this procedure causes greater than usual error in the recording.

Another disturbing factor which affects the sagittal component particularly is the so-called *proximity effect*. The fundamental *dipole theory is not fully valid* when electric impulses from the heart are recorded very near the heart, as with some thorax leads of the ordinary Ecg. In this respect, there is an especially great factor of error in the newborn as the heart is even closer to the electrode than it is in adults [123]. The dispersion of the Vcg recordings of newborn *infants is generally* greater than that in older subjects [80, 225]. Yet, Grant came to the conclusion that the potential differences which both Ecg and Vcg measure derive chiefly from the entire electrical field of the heart and not to any great extent from the part of the heart which is closest

to the electrode [74] He compared the location of the mean spatial vectors of loops recorded by the tetrahedron method and the transitional zones of scalar thorax leads and found that they were very close to one another [75] By measuring cancellation potentials, Frank concluded that the QRS complex as recorded from all parts of the human body can be considered to arise from a fixed location equivalent heart dipole to an average accuracy of 5 per cent. [64] This calls in question the existence of the proximity effect. The same conclusion was arrived at by Wilson et al. [241] Schaefer [196] and Schmitt et al. [211] who considered that on the whole the heart can be understood to correspond to one large dipole. On the other hand, Schmitt showed that vectorial lead systems now in common use discriminate by a factor of typically 2 1 between some regions within the heart. [210] The proximity effect thus cannot be ruled out completely

Mention should be made here of the two most important theoretical principles applied in developing corrected lead systems.

The systems of Schmitt and Frank are based on the *fixed-position dipole and image surface theory* [65 212] The aim is to reduce the number of errors caused by individual variations by manipulating them until they cancel out as far as possible. This can be done by placing several electrodes instead of a single one at critical points and leading the impulses of all of them to a network devised from a homogeneous and accurate model of a human torso of natural size. Methods of this kind have been described in many connections [62, 63, 67 212]

The lead field concept of McFee and Johnston is another principle on which corrected Vcg lead systems have been based [147 148, 149] If we measure the difference in potential which is recorded in the sagittal direction between two electrodes, one placed precordially and the other postcordially at the back, the maximum potential difference is usually elicited when the straight line connecting these electrodes passes via the hypothetical electrical centre point of the heart. The lead is called axial in this case. But if the straight line by passes the electrical centre point, the lead is non axial These authors showed that the field of the axial type will change considerably less than that of the non axial type when the relative position of the heart and electrodes is altered

When the sagittal potential difference is recorded by two electrodes it is nearly impossible to know axial degree of the lead employed since the position of the heart differs in different people. This problem can be solved partially and the proximity effect be partially eliminated by using several electrodes instead of only one and recording their average potentials. As the precordial electrode is the most critical, several electrodes are substituted especially for it, as in the system described by McFee and Parungao [150] Or as in Helm's system, it is replaced by a large electrode [91] If straight lines are drawn from all the precordial electrodes to the dorsal electrode, one of them will run close to the hypothetical electrical centre of the heart and is thus approximately axial Which of these electrodes is situated axially with the dorsal electrode does not influence the configuration of the Vcg loop since the impulses of all of them are combined in the resistance-combining network.

Wilson's tetrahedron system is the oldest of the Vcg systems still in use [238] The system is based on Einthoven's *principle of an equilateral triangle* This gives it the advantage of easy comparison with the Ecg findings of conventional limb leads. However it is generally agreed today that Einthoven's equilateral triangle principle is not adequate as such. The lead vectors are of different sizes and it should be replaced by a non-equilateral triangle Burger's triangle Strictly speaking, then, Wilson's Vcg system cannot by entirely adequate either

In this system the electrodes are fixed to the limbs like ordinary *Ecg limb leads*, and an additional electrode is applied on the back to the left of the 7th thoracic vertebra. This gives a *spatial figure* anatomically roughly the shape of a tetrahedron. The transverse component (X) is registered in correspondence with Ecg limb lead I. The vertical component (Y) is registered from between Wilson's central terminal (CT) and the left lower limb. The sagittal component is obtained from between CT and the dorsal electrode. The different components are amplified in agreement with different standardising coefficients so that when the coefficient of the transverse component is 1 that of the vertical component is 1.7 and of the sagittal component 1.2.

Another system which is based on *Einthoven's principle of the equilateral triangle* is that of *Milovanovich* [44]. The electrode sites in the frontal plane are the same as in the preceding system. But there are two additional thoracic electrodes for recording the sagittal component.

Burger's B W₁ system is also based on the triangular principle [24]. The electrode applications are again the same as in the conventional Ecg for recording in the frontal plane. For recording the sagittal component, the electrodes are applied to *the middle* of the chest anteriorly at the axillary level and dorsally at the same site as in Wilson's tetrahedron system. The two *systems* B_1 and B_2 previously introduced by Burger [29] are prototypes of this system.

Another principle in the application *of electrodes is anatomical orthogonality*. In the systems based on this principle the straight lines joining the electrodes are *orthogonal*.

Schellong used a simple lead system in which the electrodes were situated orthogonally three on the anterior surface of the trunk and one on the dorsal side [200]. In order to obtain a stereoscopic image the dorsal electrode was moved from above the left scapula to above the right scapula and the two loops obtained were viewed stereoscopically.

In the *double cube system* of *Duchosal and Sulzer* the electrodes are placed on the trunk surface at the four apices of an imaginary double cube [49]. The components are recorded parallel to the edges of the cube.

A much more commonly used orthogonal system is *Grishman's cube system* [79, 81, 208]. The electrodes are placed at the four apices of an imaginary cube: on the right posterior axillary line level with the second lumbar vertebra, *at the corresponding* site on the left, on the right anterior axillary line at the same level, and *above the right* scapula. The components are recorded parallel to the edges of this cube. In this, as in the preceding orthogonal systems, all the components are recorded with the same amplification so that no standardisation coefficients are necessary.

There are considerable inaccuracies in all the fairly simple methods described above. Newer *corrected systems* come nearer to the ideal that a *similar* electrical phenomenon in the

to the electrode [74] He compared the location of the mean spatial vectors of loops recorded by the tetrahedron method and the transitional zones of scalar thorax leads and found that they were very close to one another [75] By measuring cancellation potentials, Frank concluded that the QRS complex as recorded from all parts of the human body can be considered to arise from a fixed location equivalent heart dipole to an average accuracy of 5 per cent» [64] This calls in question the existence of the proximity effect. The same conclusion was arrived at by Wilson et al. [241] Schaefer [196] and Schmitt et al. [211] who considered that on the whole the heart can be understood to correspond to one large dipole. On the other hand, Schmitt showed that vectorial lead systems now in common use discriminate by a factor of typically 2:1 between some regions within the heart» [210] The proximity effect thus cannot be ruled out completely

Mention should be made here of the two most important theoretical principles applied in developing corrected lead systems.

The systems of Schmitt and Frank are based on the *fixed position dipole and image surface theory* [65, 212] The aim is to reduce the number of errors caused by individual variations by manipulating them until they cancel out as far as possible. *This can be done by placing several elec* trodes instead of a single one at critical points and leading the impulses of all of them to a network devised from a homogeneous and accurate model of a human torso of natural size Methods of this kind have been described in many connections [62, 63, 67 212]

The lead field concept of McFee and Johnston is another principle on which corrected Vcg lead systems have been based [147 148, 149] If we measure the difference in potential which is recorded in the sagittal direction between two electrodes, one placed precordially and the other postcordially at the back, the maximum potential difference is usually elicited when the straight line connecting these electrodes passes via the hypothetical electrical centre point of the heart. The lead is called axial in this case. But if the straight line by passes the electrical centre point, the lead is *non axial* These authors showed that the field of the axial type will change considerably less than that of the non-axial type when the relative position of the heart and electrodes is altered

When the sagittal potential difference is recorded by two electrodes it is nearly impossible to know axial degree of the lead employed since the position *of the heart* differs in different people. This problem can be solved partially and the proximity effect be partially eliminated by using several electrodes instead of only one and *recording their average potentials*. As the precordial electrode is the most critical, several electrodes are substituted especially for it, as in the system described by McFee and Parungao [150] Or as in Helm s system, it is replaced by a large electrode [91] If straight lines are drawn from all the precordial electrodes to the dorsal electrode, one of them will run close to the hypothetical electrical centre of the heart and is thus approximately axial. Which of these electrodes is situated axially with the dorsal *electrode does not influence the configura* tion of the Vcg loop since the impulses of all of them are combined in the resistance-combining network.

Wilson s tetrahedron system is the oldest of the Vcg systems still in use [238] The system is based on Einthoven s *principle of an equilateral tri angle* This gives it the advantage of easy comparison with the Ecg findings of conventional limb leads. However it is generally agreed today that Einthoven s equilateral triangle principle is not adequate as such. The lead vectors are of different sizes and it should be replaced by a non-equilateral triangle Burger s triangle Strictly speaking then, Wilson s Vcg system cannot by entirely adequate either

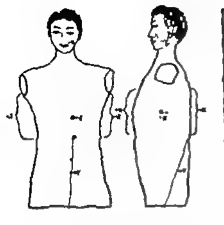

Fig. 2. Application of the electrodes in Helm system. The dotted area is covered by large sponge electrode and on the other side of the trunk there is an ordinary small electrode, placed at the corresponding site. The vertical component is recorded between the electrode on the forehead and the electrodes on the left lower limb and at the terminal point of the line marked Y on the back.

obtained as when the same skin area was covered by a single large electrode.

The positioning of the electrodes in *this system is illustrated in Fig. 2.* Sponge electrodes dipped in physiological saline solution are applied to marked sites so that they are just not interconnected. Opposite each sponge electrode is a normal metal electrode on the other side of the trunk.

Dower and Osborne were particularly anxious to evolve a method which would be as practical as possible and at the same time sufficiently accurate [45]. Their system has four electrodes, theoretically the smallest number for Vcg recording. In this system, too, the impulses are led to a resistance-combining network devised from a torso model. This set-up, according to the authors, gives very good results when the results obtained with Frank's system are used as the basis of evaluation. It is, of course *impossible to achieve exactly the same* standard of accuracy. The authors recommend the use of this system for patients in poor condition to avoid the strain of examination.

The system of McFee and Parungao [150] is based on the theory of lead field advanced by McFee and Johnston [147, 148, 149] and on the view that a roughly axial lead is easier to achieve if a series of electrodes is used rather than a single electrode (see page 12). The theoretical basis is actually not appreciably different from the principle of Helm's system.

The electrode locations are shown in Fig. 3. The transverse component is recorded between an electrode on the right flank and a pair of electrodes on the left flank. Viewed from the side they are located 1/3 of the thorax width from the anterior wall of the *thorax and are directly opposite one* another. The distance between the electrodes on the left flank in an adult of medium size is 11 cm. The sagittal component is recorded between the three precordial electrodes and the electrode at the corresponding site on the dorsal side. The precordial electrodes form an equilateral triangle. In a medium sized adult they are 6 cm from the centre of a triangle drawn directly above the centre of gravity of the ventricles. The site of course varies with the individual, *but a point* 2 cm to the left of the left margin of the sternum in the 5th *intercostal* space is selected for routine use. The

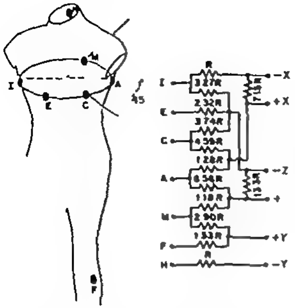

Fig. 1. Application of the electrodes and the resistance-combining network in Frank's system.

heart will always generate a Vcg loop of the same shape whatever the position of the heart and other anatomical differences.

Schmitt's SVEC III system incorporates 14 electrodes and a resistance-combining network [212]. This method gives very accurate tracings, but the great number of electrodes makes it impracticable for clinical use. It is often used for the comparison of different systems to evaluate other simpler methods.

Frank's system requires the use of seven electrodes [65]. Five are in the same horizontal plane at the level of the heart around the thorax: immediately to the front, immediately back or left of the spine, on both mid-axillary lines and 45 degrees anteriorly and to the left on the same level, and on the neck or forehead and the left lower limb. The conductors are connected with the electrical network as shown in Fig. 1. The transversal component is formed by the three thoracic electrodes, the vertical component by the electrodes of the head, back and the left lower limb and the sagittal component by all five electrodes on the chest. The placement of the electrodes is fairly simple in Frank's system and the results are quite accurate. The system is consequently widely used.

Frank and Seiden sought to evolve a simple method from Frank's system [69]. They used the same electrode location as in Wilson's tetrahedron system and a resistance-combining network designed from model measurements. They compared the results with those obtained by Frank's 7-electrode system. The results were fairly similar in some of the cases but rather divergent in others, and thus the system has not gained greater use. A detailed analysis of this system has been reported by Frank [66].

Helm's system [91] is based on the principle that more consistent lead vectors are obtained when recording between two networks of points than when recording between two individual points (see page 12). Helm had already stated this earlier [89, 90]. In other words, it is possible in this way to have fairly similar vector properties for the different parts of the heart. He also noted that when the number of electrodes placed at even distances in a certain area was increased their average potential grew at an increasingly slower rate until the curve illustrating the potentials approached the horizontal. The same potential was

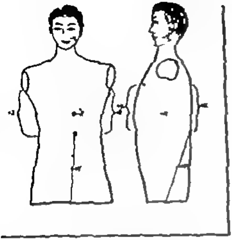

Fig. 2. Application of the electrodes in Helm system. The dotted area is covered by a large sponge electrode and on the other side of the trunk there is an ordinary small electrode, placed at the corresponding site. The vertical component is recorded between the electrode on the forehead and the electrodes on the left lower limb and at the terminal point of the line marked Y on the back.

obtained as when the same skin area was covered by a single large electrode.

The positioning of the electrodes in this system is illustrated in Fig. 2. Sponge electrodes dipped in physiological saline solution are applied to marked sites so that they are just not interconnected. Opposite each sponge electrode is a normal metal electrode on the other side of the trunk.

Helm s system [91] is based on the principle that more consistent lead vectors are obtained when recording between two networks of points than when recording between two individual points (see page 12) Helm had already stated this earlier [89 90] In other words, it is possible in this way to have fairly similar vector properties for the different parts of the heart. He also noted that when the number of electrodes placed at even distances in a certain area was increased their average potential grew at an increasingly slower rate until the curve illustrating the potentials approached the horizontal. The same potential was

McFee and Johnston and in which especially large electrodes are placed pre- and postcordially

There are unlimited alternatives for the application of the electrodes and many other methods have been tried. Over thirty lead systems have been described in the literature. The majority of them, however lack practical importance. New methods are being studied. The optimal combination of practicality and accuracy has probably still to be discovered.

COMPARISON OF DIFFERENT SYSTEMS

One difficulty in practical Vcg work is the multiplicity of the recording systems. No system is perfect. It is necessary especially when studying the newborn, to take into consideration the demands of practicality simplicity and speed in addition to theoretical faultlessness. When scalar Ecg is compared with Vcg a point often mentioned in its favour is that the placing of the electrodes is simple and clinically a well-known procedure. But it must also be remembered that no endeavour is then made to reduce the considerable factors of error which should be kept in mind in the interpretation of every Ecg curve. If the same criteria were considered adequate for the Vcg, an equally simple recording system could be used. But in order to reduce the factors of error efforts have been made to evolve new more nearly perfect systems. It is of course possible also to perform scalar recordings by corrected systems and obtain more accurate results than the routine Ecg technique gives. The multiplicity of systems is thus not a problem specific to vectorcardiography. It applies to the recording of electrical cardiac funtion in general, whether the recording technique is scalar or vectorial.

Burger et al. compared their own two systems (B_1 and B_2) with Wilson tetrahedron system [29]. As the coefficients of their systems were determined by model measurements and lead to fairly consistent results, while the results of the tetrahedron system differed more from them, these authors regarded their own methods as superior to the tetrahedron system.

Schaffer et al. compared the cube and tetrahedron systems, using a material of newborn infants [198]. The inaccuracies of both systems were approximately equal, but they decided that the tetrahedron system was more practical.

Experimenting with torso models Frank came to the conclusion that the standardisation coefficients of Wilson's tetrahedron system are too large, but that it gives more accurate results than Grishman's cube and Duchosal double cube systems [61].

Simonson et al. compared the recordings of their own SVEC III system by the scalar and vectorial techniques with Vcg loops constructed from an ordinary scalar Ecg [216]. The differences were of course considerable because of the greater potential error of ordinary Ecg and the difficulties involved in constructing Vcg loop with even approximate accuracy from scalar curves.

Recordings were performed by Abildskov and Pence using the tetrahedron system and the corrected system of McFee and Johnston [1]. The results obtained by the latter were much more consistent. The normal recordings were usually fairly similar but if there was an unusually great axis deviation to the right the tetrahedron recording showed very marked dispersion.

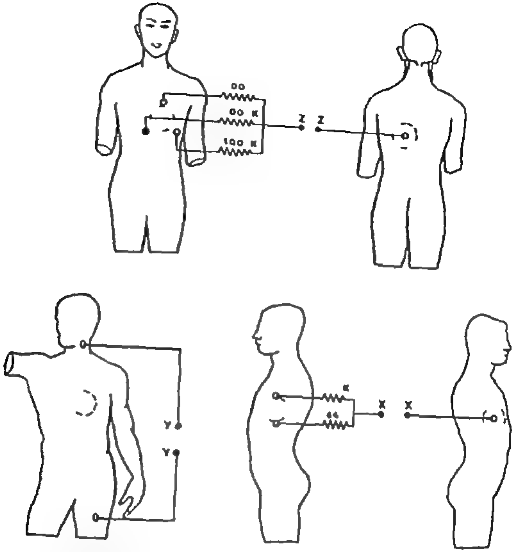

Fig. 3. Application of the electrodes and the resistance-combining network in the system of McFee and Parungao.

vertical component is recorded between the electrodes on the left lower limb and on the left of the neck. A simple resistance-combining network is used, which is also shown in the Fig. 3.

In the system introduced by *Halmos et al.* the electrode locations are not fixed anatomically but are applied according to the position of the heart [86] This system is anatomically orthogonal.

Of the *other recording systems* mention may be made of Kimura's orthogonal system which is still in use in Japan [116] Milnor's orthogonal system [152 154] Akulynchev's system, almost the only one used in Russia [3] in which, differently from all the other systems, recording is at five planes and the electrodes are located in roughly the form of a pyramid, and Barber's system [14] which is based on the lead field concept of

McFee and Johnston and in which especially large electrodes are placed pre- and postcordially

There are unlimited alternatives for the application of the electrodes and many other methods have been tried. Over thirty lead systems have been described in the literature. The majority of them, however lack practical importance. New methods are being studied. The optimal combination of practicality and accuracy has probably still to be discovered.

It is necessary especially when studying the newborn, to take into consideration the demands of practicality simplicity and speed in addition to theoretical faultlessness. When scalar Ecg is compared with Vcg a point often mentioned in its favour is that the placing of the electrodes is simple and clinically a well-known pocedure. But it must also be remembered that no endeavour is then made to reduce the considerable factors of error which should be kept in mind in the *interpretation* of every Ecg curve. If the same criteria were considered adequate for the Vcg, an equally simple recording system could be used. But in order to reduce the factors of error efforts have been made to evolve new more nearly perfect systems. It is of course possible also to perform scalar *recordings by corrected* systems and obtain more accurate results than the routine Ecg technique gives. The multiplicity of systems is thus not a problem specific to vectorcardiography It applies to the recording of electrical cardiac funtion in general, whether the recording technique is scalar or vectorial.

Burger et al. compared their own two systems (B_1 and B_2) with Wilson tetrahedron system [29] As the coefficients of their systems were determined by model measurements and lead to fairly consistent results, while the results of the tetrahedron system differed more from them, these authors regarded their own methods as superior to the tetrahedron system.

Schaffer et al. compared the cube and tetrahedron systems, using a material of newborn infants [198] The inaccuracies of both systems were approximately equal, but they decided that the tetrahedron system was more practical.

Experimenting with torso models Frank came to the conclusion that the standardisation coefficients of Wilson's tetrahedron system are too large, but that it gives more accurate results than Grishman's cube and Duchosal's double cube systems [61]

Simonson et al. compared the recordings of their own SVEC III system by the scalar and vectorial techniques with Vcg loops constructed from an ordinary scalar Ecg [214] The differences were of course considerable because of the greater potential error of ordinary Ecg and the difficulties involved in constructing Vcg loop with even approximate accuracy from scalar curves.

Recordings were performed by Abildskov and Pence using the tetrahedron system and the corrected system of McFee and Johnston [1]. The results obtained by the latter were much more consistent. The normal recordings were usually fairly similar but if there was an unusually great axis deviation to the right the tetrahedron recording showed very marked dispersion.

Burger *et al.* compared two systems based on the tetrahedron technique but in which the sagittal component was determined between CT and a dorsal electrode or a thoracic electrode [30] Provided suitable coefficients were selected, the results of both systems were fairly similar The authors recommended for general use also coefficients that can be determined by calculation or experimentally They claimed in another context, that any well founded Vcg system can be converted with the help of coefficients to make it comparable with another system without changing the location of the electrodes [25] Such a conversion cannot be achieved by changing the placement of the electrodes [24]

Dower and Osborne compared the system introduced by Frank and Seiden and their own system, using Frank s 7-electrode system as the criterion [45] Four electrodes are used in both systems, the aim being simplicity They found that their own system was superior and recommended it for patients in poor condition.

Four very accurate systems, viz. those of Schmitt, Frank, McFee and Parungao and Helm, were compared by *Langner et al.* [128] All four gave fairly consistent results *for the majority of the test objects*, but whenever there was a greater degree *of* divergence it occurred in the sagittal component and was generally seen in abnormal recordings. When this occurred, the Schmitt and Frank recordings were similar to one another and those performed according to Helm and McFee were like one another This could be expected from the theoretical bases of the systems.

Pipberger performed orthogonal Ecg and Vcg recordings on 100 normal persons using Schmitt s SVEC III system. He compared the results with Ecg curves obtained with conventional leads. The dispersion in the frontal plane was about 50 per cent smaller in the SVEC III curves when assessed on the basis *of the maximal QRS vector* [174]

Burger et l. compared results that they obtained using Frank s, Schmitt s and their own system (B_1W_4) [31] The correlation between the Frank and Schmitt systems was fairly good, while their own system gave results which differed *materially from them.* It must be remembered, *however that fewer* electrodes are used in their own system than in the other two. They emphasised that the sagittal component of the heart vector is the most difficult to record.

Comparing the systems of Kimura and of Grishman (cube) Kimura and Toshima noted that the former was more sensitive to hypertrophy of the left and the latter to hypertrophy of the right heart [117]

The practical value of Frank s and McFee s and of the cube and tetrahedron systems *for* infants and children was studied by Hayashi and Takarada. *They* stated that the Frank lead system of vectorcardiography seemed to be applicable, roughly without distortions, to the majority of infants and children, regardless of healthy or sick ones [87]

Helm and Te-Chuan Chou experimented with changing the dipole location of corrected and uncorrected vectorcardiographic leads, using Frank s system as the corrected and a *slightly modified* cube system as the uncorrected system [93] Although the loop configuration failed in both systems to remain unaltered when the dipole location was changed, Frank s method proved superior The experiments were conducted on a torso model.

It is difficult to find adequate standards for evaluating the reliability of the different systems. For instance a basis commonly used is the degree of *similarity* as compared with the results obtained by methods generally recognised as good. In some cases the comparison *has* been with *loops* or mean vectors constructed from an ordinary Ecg [87 214 216] Another standard *that has been used is the* consistency of the results obtained by a method for a consistent test group. Pair determinations on the same sub-

ject form a still more *critical* basis. In the author's opinion, the latter two are *the only* unbiased criteria since systems based on the same theoretical foundation usually give fairly similar results irrespective of how accurate they are. Furthermore, it can probably be assumed from the studies cited here that when one's own method is compared with another the former is usually found superior.

ELECTROCARDIOGRAPHIC STUDIES ON THE NEWBORN

Electrocardiographic studies on full-term newborn

The electrical activity of the heart of the newborn has been studied extensively with the aid of scalar Ecg. Certain special features have been discerned compared with recordings made later in life. Consequently it is not correct to draw a line between the normal and the pathologic according to the same rules.

Normal Ecg values of the newborn have been reported by e.g. Hori et al. [101], Groedel and Miller [82], Ashman and Hull [10], Joly and Combe [110], Schaffer et al. [199], Ziegler [248], Datey and Bharucha [39], Kessel [114], Heck and Stoermer [88], Michaelsson [151], Rothfeld et al. [189], Nadas [157], Wasserburger [232] and Walsh [227]. The Ecg of the newborn differs from the Ecg later in life in many ways. The most important of these differences are:

Preponderance of the right heart which in older subjects would be taken as a sign of pathologically marked right axis deviation or right ventricular hypertrophy. It is a physiologic phenomenon in the newborn, associated with the anatomic size of the ventricles and their work output. According to Ziegler, both ventricles of the heart are of roughly equal weight in a fetus of 24—28 weeks and their work output, obviously, is also the same [250]. Emery and MacDonald stated that there is left ventricular preponderance in the fetus until the age of 24 weeks [57]. After 24—28 weeks of fetal age, the mass of the right ventricle grows relatively more rapidly in weight and at the time of birth is heavier, though only slightly heavier, than the left ventricle. However, the wall of the left ventricle is thicker than that of the right already at this time. After birth, the left ventricle grows more rapidly than the right and the adult weight ratio between the right and left heart is reached at the age of c. 6 months [250]. Keen found that the left heart was heavier than the right heart at the age of 4 weeks in a newborn delivered at term [113]; this has been confirmed by Emery and Mithal [58].

Abnormally high peaked P waves have been demonstrated in newborn normally during the first three days of life [38]. P waves over 2.5 mV in height and longer than 0.07 sec. in duration have been regarded as pathologic in the newborn [157, 199]. The duration of the P wave increases with age as the auricular mass increases.

A prominent Q wave in healthy newborn in leads II and III has been noted by several workers [101 110 114 119 219] A Q wave in lead V_1 is considered to signify hypertrophy of the right heart in the newborn as well [146 157] Walsh stated that the presence of a Q wave in V_1R is normal though rare [228]

The T wave is of special interest in the newborn. It is normally positive in lead V_1 during the first day of life and then negative for several years. This was attributed by Ziegler to elevation of pressure in the right heart [249] Stern and Lind noted that the inversion of the T wave occurs over a wide range of neonatal age from about 30 min. to 96 hours in a material of 32 children [218] Later in the neonatal period the positive T wave is always pathologic in lead V_1 [120] The newborn often shows very low T waves in the limb leads [151] The very early neonatal Ecg changes were studied by Hait and Gasul. They found that the T wave was negative at the age of under 5 min. in lead V_1 and positive after it, maximally at the age of 6 hours [84] They attributed this to transient ischemia or at least overloading of the right heart.

The PR interval is much shorter in the newborn than later in life. But prolonged PR intervals have been reported during the first week, and especially during the first hour of life [41 191 228] It has been assumed that this is due to the immaturity of the conduction system [191]

The QT interval may be prolonged in some healthy newborn during the first days of life [151]

The QRS interval is naturally shorter in the newborn than in older subjects since it depends on the volume of the cardiac muscle mass. It, too, is sometimes longer than normal in the first week of life [41] as is the *ST segment* [228]

Arrhythmias are more frequent in the newborn than in later life. Michaelsson's study showed a very high incidence of sinus arrhythmias and supraventricular arrhythmias in newborn infants [151] In contrast, extrasystoles occur more rarely in newborn than in older subjects [124, 156]

No difference was observed by Ringel between the electrocardiograms of a normal and an asphyxiated newborn [186] but Stern and Lind reported a more marked deviation to the right of the electrical axis of the heart in asphyxiated newborn infants [219] In studies on the isolated right auricle of the rabbit Hirvonen stated a prolonged QRS interval, lowered R deflection and a retarded beat rate in anoxia [95] No significant differences have been noted before and after the newborn infant's first cry [251] Electrocardiograms taken during the fetal period and again after birth have revealed no major or sudden changes in connection with birth [109 220 231] Nor have any such changes in heart rhythm been noted [73] Birth obviously places no exceptionally great strain on the infant's heart. Adams and Lind showed by catheterisation that postnatal pressure variations in the heart occur only gradually in the course of a few days [2] and not instantaneously as had

been earlier assumed. The decrease in pulmonary arterial pressure after respiration has begun spontaneously was studied by Peltonen and Hirvonen in lambs born by cesarean section [168]. No sudden changes occurred. The volume of blood in the lungs of young lambs increases by only c. 20—30 per cent after the first breath of life, and not for 24—36 hours is a 100 per cent increase observed [4]. The situation is the same with both aortic and pulmonary arterial pressure, no rapid pressure changes occur perinatally [96, 168]. Nor are the fetal circulatory shunts closed instantaneously after birth [97, 98, 164, 165, 166, 167, 168, 169, 170]. It is understandable, then, that the Ecg displays no acute changes in connection with birth. An exception, however, is the alterations in the T wave in infants during the first minutes of life [84]. But the Ecg changes during the neonatal period are much more rapid than they are later and the dispersion of normal values is greater. Hence, it is often more difficult to distinguish between normal and pathologic at this time than later in life. Recording of serial tracings is therefore recommended in doubtful cases [230].

Electrocardiographic studies on prematures

Whether the Ecg of the newborn premature has certain typical features to distinguish it from that of a full-term baby is a matter that has engaged the attention of many authors for some time. In 1913, Noeggerath came to the conclusion that good cardiac function is generally associated with a normal electrocardiogram, whereas premature or otherwise weak babies may give abnormal curves [160]. Räihä came to a similar conclusion in his study on electrocardiography of premature infants [190]. He also noted that so-called primitive curves with low P and T waves and, occasionally abnormally low amplitudes in all waves, were often encountered in prematures. The same observation was made by e.g. Burghard and Wunnerlich [33].

The electrical axis of the heart shows a smaller deviation to the right during the first weeks of life in the premature than in the full-term newborn [190, 192, 224]. The very low waves of the QRS complex registered in some prematures during the first week of life do not persist, but change to normal at the age of 1—2 weeks [227]. In the thorax leads on the left, prematures display a higher R wave and deeper Q wave on the average than are seen in newborn delivered at term [193].

The PR interval is slightly shorter in newborn prematures, 0.092—0.1 seconds [221, 224], than in full-term infants of the same age, 0.08—0.12 seconds [18, 82, 83, 114], although prolonged intervals are recorded for both, especially during the first week of life [41, 191, 192, 224].

The QRS interval is also a little shorter in the premature newborn. 0.050 seconds may be regarded as the

A prominent Q wave in healthy newborn in leads II and III has been noted by several workers [101 110 114 119 219] A Q wave in lead V_1 is considered to signify hypertrophy of the right heart in the newborn as well [146 157] Walsh stated that the presence of a Q wave in V_4R is normal though rare [228]

The T wave is of special interest in the newborn. It is normally positive in lead V_1 during the first day of life, and then negative for several years. This was attributed by Ziegler to elevation of pressure in the right heart [249] Stern and Lind noted that the inversion of the T wave occurs over a wide range of neonatal age from about 30 min. to 96 hours in a material of 32 children [218] Later in the neonatal period the positive T wave is always pathologic in lead V_1 [120] The newborn often shows very low T waves in the limb leads [151] The very early neonatal Ecg changes were studied by Hait and Gasul. They found that the T wave was negative at the age of under 5 min. in lead V_1 and positive after it, maximally at the age of 6 hours [84] They attributed this to transient ischemia or at least overloading of the right heart.

The PR interval is much shorter in the newborn than later in life But prolonged PR intervals have been reported during the first week, and especially during the first hour of life [41 191 228] It has been assumed that this is due to the immaturity of the conduction system [191]

The QT interval may be prolonged in some healthy newborn during the first days of life [151]

The QRS interval is naturally shorter in the newborn than in older subjects since it depends on the volume of the cardiac muscle mass. It, too is sometimes longer than normal in the first week of life [41] as is the *ST segment* [228]

Arrhythmias are more frequent in the newborn than in later life Michaëlsson's study showed a very high incidence of sinus arrhythmias and supraventricular arrhythmias in newborn infants [151] In contrast, extrasystoles occur more rarely in newborn than in older subjects [124 156]

No difference was observed by Ringel between the electrocardiograms of a normal and an asphyxiated newborn [186] but Stern and Lind reported a more marked deviation to the right of the electrical axis of the heart in asphyxiated newborn infants [219] In studies on the isolated right auricle of the rabbit Hirvonen stated a prolonged QRS interval, lowered R deflection and a retarded beat rate in anoxia [95] No significant differences have been noted before and after the newborn infant's first cry [251] Electrocardiograms taken during the fetal period and again after birth have revealed no major or sudden changes in connection with birth [109 220 231] Nor have any such changes in heart rhythm been noted [73] Birth obviously places no exceptionally great strain on the infant's heart. Adams and Lind showed by catheterisation that postnatal pressure variations in the heart occur only gradually in the course of a few days [2] and not instantaneously as had

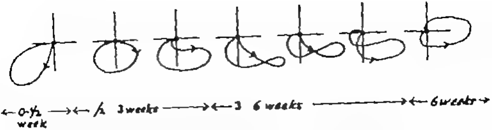

Fig. 4. A series of horizontal QRS loops recorded by Elek *et al.* by the double cube method [53]. The loops display typical changes of infancy and early childhood.

distinct signs of hypertrophy of the right heart. Progressive changes in the Vcg began to appear from age of a few days, and at 1 month the differences from the recordings of the first days of the infant's life were fairly distinct. Individual differences were great. Slower progression occurred from the age of 3 months on. The authors realised the inadequacy and inaccuracy of the methods employed for study of the newborn, particularly as regards the horizontal projection, which varied over an extremely great range in the tetrahedron system, and the greatly exaggerated right heart effect obtained in the cube system. In contrast, the frontal loop recorded by the cube system was more to the left and much smaller than that recorded by the tetrahedron system. Very great dispersion was obtained by both methods. There was no progression in the T wave during the neonatal period. Labrunie tried to construct the Vcg loops from the scalar Ecgs of a fairly small group of newborn and arrived at results which resembled the above in their main outlines. The dispersion was very great and the results rather summary [121].

Rothfeld *et al.* [189] and Wachtel *et al.* [225] studied 50 healthy infants immediately after delivery and 31 of them at the age of 1 month, using the cube system. The finding for normal newborn under 48 hours old was reminiscent of hypertrophy of the right heart, as in other studies, but with the difference that in these studies the QRS and T loops were almost always concordant at all planes and that the direction of inscription of the QRS loop was generally clockwise at the sagittal plane. As variations, these authors mentioned the cases in which the QRSaE loop was left, superior or posterior or in which the direction of inscription of its frontal or horizontal projections was counter-clockwise.

Using the cube system, Calleja *et al.* made 166 Vcg tracings of 154 children, some of whom were newborn [34]. They found that the development of the finding with age was seen best in the horizontal projection, although no manifest development could be stated during the neonatal period. The average angle formed by the mean QRS vector and the ground line immediately after delivery and at the age

upper limit [222, 224] while for full-term babies it is 0.065 seconds [88].

Besides the low *P waves* already mentioned, prematures often have high and peaked P waves [227, 234] and sometimes negative P waves in leads V_1 and V_2 [193].

Although the *T wave* in lead V_1 is generally positive in newborn delivered at term during the first day of life except for the first few minutes [84], it is often negative in the first day of life of prematures [193]. Prematures have biphasic and negative T waves in all bipolar leads more often than newborn delivered at term [182, 193].

Arrhythmias in newborn prematures have been studied recently by means of continuous recording on magnetophone tape. Morgan *et al.* studied 20 normal prematures aged from 5 hours to 29 days [155]. Many sinus arrhythmias were elicited from 5-hour recordings. Nearly half of the prematures had a rhythm that was 50 per cent slower than normal, and five infants had in addition one or more periods of especially slow bradycardia, i.e. under 50/min. Bradycardia generally occurs during sleep, sometimes in connection with defecation. Välimäki noted transient sinus bradycardia in almost every premature when the continuous recording was performed sufficiently long [246].

Thus, although there are certain electrocardiographic differences between the premature and full-term newborn, they are not the rule and they are not typical enough to warrant the listing of definite Ecg characteristics of premature infants.

EARLIER STUDIES OF THE VECTORCARDIOGRAM OF THE NEWBORN

Several workers have studied the Vcg of infants, but the materials have usually been small and most of the recording systems used have been the old ones which are too inaccurate for reliable results, especially with newborn infants. No uniform idea has been formulated concerning the vectorcardiographic technique and the results for normal newborn.

Schaffer and Beinfield studied 35 newborn by Grishman's cube system and established a pattern similar to that seen in older persons with hypertrophy of the right heart [197]. Forty-seven infants were studied by Elek *et al.* using the double cube system of Duchosal and Sulzer. They reported the same phenomenon and drew attention to the accentuation of the potentials of the left heart from the age of 20—30 days onwards [52]. The age of the subjects in this material was from 2 days to 2 years. The authors described the development of the Vcg finding in healthy full-term infants as is depicted in Fig. 4.

The cube system was used by Doll, too, in his study of 61 newborn. He also established the same type as in hypertrophy of the right heart later [42].

Rosen and Gardberg introduced the largest material so far, 300 infants, aged 1 day to 1 month [188]. The vectorcardiograms were made by Grishman's cube and Wilson's tetrahedron systems. Again, there were

term infants; c) more right ventricular dominance at the age of 72 hours and one week than in full term infants; and d) greater variability in all age groups but especially during the first week of life. [139]

Fowler made Vcgs of 50 normal infants *from birth to 1 year of age*. He used an Electronics for Medicine DR-8 recorder which gives results reproducible with the Frank lead system. The dispersion was greatest in the youngest infants. The spatial QRS-T angle (see p. 28) at an age of under 2 months was 71 degrees, standard deviation 29 degrees. There were no distinct differences between the different age groups in the magnitude of the instantaneous and maximal vectors. [60]

ANALYSIS OF VECTORCARDIOGRAPHIC FINDINGS

QRSsE *half area vector*

Maximal vector, half time vector and half area vector etc. have been used in the attempt to find vectors that characterise Vcg loops. The aim has been to find a vector that is as consistent as possible with the so-called mean vector which is the integration of the magnitude and time of all spatial instantaneous vectors during QRS. The approximate mean vector can be determined from scalar Ecg by indicating the superficial areas of the waves by vectors and from Vcg by taking the mean of a number of instantaneous vectors determined at even and very short intervals [173]. Pipberger determined in this way the mean spatial QRS vectors for 34 *persons* and obtained values which were close to the mean vectors obtained from scalar Ecg [173]. *He noted* in the same study that maximal vectors and half time vectors were inconsistent and inaccurate when compared with mean vectors. On the other hand, half area vectors showed extremely good correlation with mean vectors as regards vector direction. Accuracy was increased by averaging the 3 planar vectors. This can be done by calculating the mean time for *half* area vectors on each plane. Other authors, too, have reported that the half area vector is more stable than the maximal vector especially in sagittal and horizontal projections [105].

QRSsE polar vector

The QRSsE loop is usually on roughly the same plane, the so-called QRS plane (152, 175, 187, 201). The position of this plane naturally varies in individuals, which increases the variations of the QRS loop on the ordinary recording planes. But if the QRS loop is examined on its own plane the range of variation is much smaller [152, 175, 185]. It is fairly easy in *practice to determine* the plane in question and the projection of the QRSsE loop on it by *using a vector loop rotator or resolver* [209]. Burger and Vaane *introduced the concept* of polar vector. It means a vector perpendicular to the QRS plane; its base is at the zero point of the QRSsE loop and its length is directly proportional to the area of the QRS

of 1 month was +90 and +60 degrees in the frontal projection +53 and +57 degrees in the sagittal projection, and +85 and +40 degrees in horizontal projection. The progressive turning of the mean QRS vector to the left and posteriorly continued after this in the tracings taken at the age of 3 months. The dispersion of the results was greatest in the youngest group

Vcgs of 90 normal newborn were taken by Namin *et al.* by Frank's system [159] The angle formed by the mean frontal QRS vector and the ground line was 138 ± 33.6 degrees during the first day of life subsequently turning progressively to the left. The initial 0.005 instantaneous vector was determined in the horizontal projection and its direction immediately after birth was 89 ± 23 degrees; it then turned progressively to the right. The direction of inscription of the QRS loop in the horizontal projection was counter-clockwise in 10 infants, clockwise in the others. The mean T axis was chiefly anterior on the first day of life subsequently turning to the left. DePasquale and Burch made Vcg recordings of 50 newborn by the tetrahedron system [41] They observed that the TsE loop deviated progressively from right to left during the first 86 hours of the infant's life

Schmitt's Vcg system has also been used for vectorcardiographic study of the newborn. It was employed by Elliott *et al.* on 50 infants. One of their findings was that the direction of inscription of the horizontal projection in the newborn was almost always clockwise as established by other systems, too [55]

Using Frank's system, Namin *et al.* took Vcgs of 107 normal infants aged from a few hours to 18 months [158] They made serial tracings for some of the infants. The under 1 month age group revealed a very great dispersion. These authors contend that serial tracings must always be done for the newborn in ambiguous cases.

A very interesting experiment was performed by Idriss et al. on mongrel bitches. Applying Frank's system, and using a special surgical technique they made Vcg tracings before birth and followed the changes occurring after birth. The maximal QRS vector was directed upwards to the right and anteriorly before birth. The changes occurred gradually and not instantaneously during the transition to extrauterine environment, and it was not until the 2nd day of life that the maximal QRS vector was directed increasingly down to the left as in the second week of life Only minimal alterations occurred in the pressure of the right heart during the transition to extrauterine environment. [109] The same phenomenon in regard to pressure has been established in human beings (see p. 20)

Liebman *et al.* used Frank's system to make Vcgs of 50 normal prematures at the age of 24 hours, 72 hours, one week and one month. They continued the study beyond the neonatal period. Their most important results were as follows. a) smaller voltages than for infants born at term b) less right ventricular dominance at the age of 24 hours than in full

term infants; c) more right ventricular dominance» at the age of 72 hours and one week than in full-term infants; and d) greater variability in all age groups but especially during the first week of life. [139]

Fowler made Vcgs of 50 normal infants from birth to 1 year of age. He used an Electronics for Medicine DR-8 recorder which gives results reproducible with the Frank lead system. The dispersion was greatest in the youngest infants. The spatial QRS-T angle (see p. 26) at an age of under 2 months was 71 degrees, standard deviation 29 degrees. There were no distinct differences between the different age groups in the magnitude of the instantaneous and maximal vectors. [60]

ANALYSES OF VECTORCARDIOGRAPHIC FINDINGS

QRSsÊ half area vector

Maximal vector, half time vector and half area vector etc. have been used in the attempt to find vectors that characterise Vcg loops. The aim has been to find a vector that is as consistent as possible with the so-called mean vector which is the integration of the magnitude and time of all spatial instantaneous vectors during QRS. The approximate mean vector can be determined from scalar Ecg by indicating the superficial areas of the waves by vectors and from Vcg by taking the mean of a number of instantaneous vectors determined at even and very short intervals [173]. Pipberger determined in this way the mean spatial QRS vectors for 34 persons and obtained values which were close to the mean vectors obtained from scalar Ecg [173]. He noted in the same study that maximal vectors and half time vectors were inconsistent and inaccurate when compared with mean vectors. On the other hand, half area vectors showed extremely good correlation with mean vectors as regards vector direction. Accuracy was increased by averaging the 3 planar vectors. This can be done by calculating the mean time for half area vectors on each plane. Other authors, too have reported that the half area vector is more stable than the maximal vector especially in sagittal and horizontal projections [105].

QRSsÊ polar vector

The QRSsÊ loop is usually on roughly the same plane, the so-called QRS plane (152, 175, 187, 201). The position of this plane naturally varies in individuals, which increases the variations of the QRS loop on the ordinary recording planes. But if the QRS loop is examined »on its own plane» the range of variation is much smaller [152, 175, 185]. It is fairly easy in practice to determine the plane in question and the projection of the QRSsÊ loop on it by using a vector loop rotator or resolver [209]. Burger and Vaane introduced the concept of polar vector. It means a vector perpendicular to the QRS plane: its base is at the zero point of the QRSsÊ loop and its length is directly proportional to the area of the QRS

of 1 month was +90 and +60 degrees in the frontal projection, +53 and +57 degrees in the sagittal projection, and +85 and +40 *degrees in horizontal* projection. The progressive turning of the mean QRS vector to the left and posteriorly continued after this in the tracings taken at the age of 3 months. The dispersion of the results was greatest in the *youngest* group.

Vcgs of 90 normal newborn were taken by Namin *et al.* by Frank s system [159] The angle formed by the mean frontal QRS vector and the ground line was 138 ± 33.6 degrees during the first day of life subsequently turning progressively to the left. The initial 0 005 instantaneous vector was determined in the horizontal projection, and its direction immediately after birth was 89 ± 23 degrees it then turned progressively to the right. The direction of inscription of the QRS loop in the hori zontal projection was counter-clock wise in 10 infants, clockwise in the others. The mean T axis was chiefly anterior on the first day of life subsequently turning to the left. DePasquale and Burch made Vcg recordings of 50 newborn by the tetrahedron system [41] They observed that the TsE loop deviated progressively from right to left during the first 86 hours of the infant s life.

Schmitt s Vcg system has also been used for vectorcardiographic study of the newborn. It was employed by Elliott *et al.* on 50 infants. One of their findings was that the direction *of inscription of the* horizontal projection in the newborn was almost always clockwise as established by other systems, too [55]

Using Frank s system Namin *et al. took Vcgs of 107 normal infants* aged from a few hours to 18 months [158] They made serial tracings for some of the infants. The under 1-month age group revealed a very great disper sion. These authors contend that serial *tracings must always be done for the newborn in ambiguous cases.*

A very interesting experiment was performed by Idriss *et al.* on mongrel bitches. Applying Frank s system, and using a special surgical technique they made Vcg tracings before birth and followed the changes occurring after *birth. The maximal* QRS vector was directed upwards to the right and anteriorly before birth. The changes occurred gradually and not instant aneously during the transition to extra uterine environment, and it was not until the 2nd day of life that the maximal QRS vector was directed increasingly down to the left as in the second week of life Only minimal alterations occurred in the pressure of the right heart during the transition to extrauterine environment. [109] The same phenomenon in regard to pressure has been established in human beings (see p 20)

Liebman *et al.* used Frank s system to make Vcgs of 50 normal prematures at the age of 24 hours, 72 hours, one week and one month. They continued the study beyond the neonatal period. Their most important results were as follows a) smaller vol tages than for infants born at term b) less right ventricular dominance at the age of 24 hours than in full

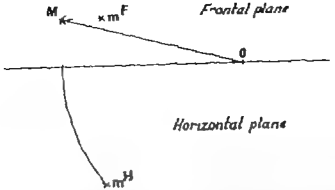

Fig. 5. Revolution to determine the spherical coordinates and spatial magnitude of vector according to Brinberg (19). m^F and m^H are the projections of the terminus of the vector in the frontal and horizontal planes. The azimuth is measured directly from the horizontal projection. The spatial vector is then assumed to be turned into the frontal plane so that its magnitude and the angle formed by it with the horizontal plane remain unchanged. Thus gives vector OM. Its magnitude is the same as the spatial magnitude of the original vector. Elevation is the angle between vector OM and the ground line.

changes of the heart, but is determined solely by the properties of the myocardium [76].

The spatial QRS-T angle can be determined by many methods. It can be calculated from the projections of the mean QRS and T vectors on the planes as follows:

If
V_1 = the spatial magnitude of the mean QRS vector
X_1, Y_1 and Z_1 = the scalar magnitudes of the above,
V_2 = the spatial magnitude of the mean T vector and
X_2, Y_2 and Z_2 = the scalar magnitudes of the above
we obtain

$$V_1 = \sqrt{X_1^2 + Y_1^2 + Z_1^2} \text{ and}$$

$$V_2 = \sqrt{X_2^2 + Y_2^2 + Z_2^2}$$

If we use the expression of the scalar product of the vectors, we obtain the spatial QRS-T angle (φ) as follows:

$$\cos \varphi = \frac{X_1X_2 + Y_1Y_2 + Z_1Z_2}{V_1V_2}$$

Langner constructed a geometrical model which can be used to determine the directions of the mean spatial vectors and the angles between them [125]. The spatial QRS-T angle is obtained very simply from the tables compiled by Helm and Fowler in which the QRS-T angles on different planes are entered [92]. The spatial angle is then obtained through a simple process of calculation. According to Brinberg, the spatial QRS-T angle is determined in the following way: The mean QRS and T vectors and the line which connects their termini form a triangle in space. The projections of the termini of both vectors on the frontal and horizontal planes are known. Their true lengths, as well as the true length of the segment of the line connecting their termini, are determined by revolution (Fig. 5) from the projections men-

loop in the projection on its own plane Seen from the direction of this vector the direction of inscription of the loop is counter-clockwise They found that the direction of the polar vector was often so different from normal in persons with heart disease that it was of diagnostic significance. [32] Polar vector was regarded by Pipberger and Carter as the best indicator between a normal and pathologic record. If the shape and principal axis of QRS and the QRS-T angle on the QRS plane were considered in addition, it was possible to establish pathologic records with 85—100 per cent reliability when using the corrected systems of Frank and Schmitt. [175]

Spatial QRS-T angle

A very important point in studying the ventricular complex of electrocardiogram is the relationship between the waves caused by depolarisation and repolarisation and the entity they constitute As early as 1934 Wilson et al. noted the areas of the waves of the ventricular complex [240] By measuring separately the surface areas on the positive and negative side planimetrically and deducting the smaller from the greater they obtained a quantity which they termed the ventricular gradient. The gradient is then naturally a planar gradient on the plane in question. By using tracings on different planes it is possible to determine also the spatial gradient. As the ventricular gradient has both a direction and a magnitude, it can be illustrated with a vector This has since become one of the most important quantitative values in Ecg analysis.

Determination of the ventricular gradient from the scalar Ecg and the factors affecting it were studied by Ashman and his co-workers [6 7 8 9] Simonson *et al.* stress the significance of spatial ventricular gradient [215] The ventricular gradient of infants was determined by DePasquale and Burch [40] though the material was small. Preponderance of the right heart was naturally revealed and the ventricular gradient was longer during the first three years than later

When analysing a vectorcardiogram it is no simple matter to determine the *ventricular gradient* chiefly because of the difficulty of determining the *duration of the T loop* As the ventricular gradient is a concept integrated with time very careful determination of time is necessary However the mutual relationship between the QRSsÊ and TsÊ loops is of equal significance in Vcg diagnosis as in scalar Ecg. This ratio is illustrated by the *spatial QRS T angle* which refers to the spatial angle constituted by the mean QRSsÊ vector and the mean TsÊ vector Its use as a fundamental criterion in Vcg interpretation was suggested by Pipberger *et al* [177 178] and Grant *et al.* [77]

The QRS-T angle is affected to some extent by the same factors as the ventricular gradient. The QRS-T angle increases very typically in many pathologic conditions, such as hypertrophies, bundle branch blocks, electrolyte disturbances and *infarctions*. It is not influenced by the positional

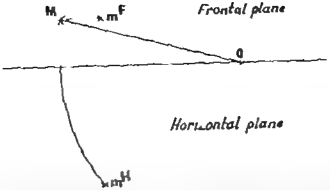

Fig. 5. Revolution to determine the spherical coordinates and spatial magnitude of vector according to Brinberg (18) m^F and m^H are the projections of the terminus of the vector m the frontal and horizontal planes. The azimuth is measured directly from the horizontal projection. The spatial vector is then assumed to be turned into the frontal plane so that its magnitude and the angle formed by it with the horizontal plane remain unchanged. This gives vector OM. Its magnitude is the same as the spatial magnitude of the original vector. Elevation is the angle between vector OM and the ground line.

changes of the heart, but is determined solely by the properties of the myocardium [76]

The spatial QRS-T angle can be determined by many methods. It can be calculated from the projections of the mean QRS and T vectors on the planes as follows:

If

V_1 = the spatial magnitude of the mean QRS vector

X_1, Y_1 and Z_1 = the scalar magnitudes of the above,

V_2 = the spatial magnitude of the mean T vector and

X_2, Y_2 and Z_2 = the scalar magnitudes of the above

we obtain

$$V_1 = \sqrt{X_1^2 + Y_1^2 + Z_1^2} \text{ and}$$

$$V_2 = \sqrt{X_2^2 + Y_2^2 + Z_2^2}$$

If we use the expression of the scalar product of the vectors, we obtain the spatial QRS-T angle (φ) as follows:

$$\cos\varphi = \frac{X_1X_2 + Y_1Y_2 + Z_1Z_2}{V_1V_2}$$

Langner constructed a geometrical model which can be used to determine the directions of the mean spatial vectors and the angles between them [125]. The spatial QRS-T angle is obtained very simply from the tables compiled by Helm and Fowler in which the QRS-T angles on different planes are entered [97]. The spatial angle is then obtained through a simple process of calculation. According to Brinberg, the spatial QRS-T angle is determined in the following way. The mean QRS and T vectors and the line which connects their termini form a triangle in space. The projections of the termini of both vectors on the frontal and horizontal planes are known. Their true lengths, as well as the true length of the segment of the line connecting their termini, are determined by revolution (Fig. 5) from the projections men-

tioned. When all the sides of the triangle are now known, the angles are obtained by calculation. [19] Another possibility is to determine the spherical coordinates of the axes of the mean QRS and T vectors by rev olution and to mark them on the spherical surface so that the spatial angle between them can be measured by a movable meridian.

The spatial QRS-T angle of 50 nor mal adults determined by Ball and Pipberger was 56 ± 18.8 the maxi mum and minimum were 20 and 105 degrees [13] Rothfeld *et al.* determined the QRS-T angle of 50 newborn in plane projections and reported it to be under 40 degrees on the frontal and sagittal planes in the majority of the cases (c. 80 per cent) and on the horizontal plane in a little over half the cases [189] Babej and Lívancová—Brožová [12] and Hiraya ma [94] stated that the QRS-T angle is largest in the neonatal period.

Other aspects of analysis

In addition to the measurable quan tities mentioned in the preceding paragraphs, several other quantities that illustrate better or less well cer tain properties of Vcg loops have also been employed for statistical and com parative work.

Several workers have determined the superficial area of the QRS loop. A simplified method has been used for this purpose by Marini [144] The body of the loop is taken to be roughly rectangular L × V in area, when L = length and W = width. The intrinsic and terminal parts are assumed to be approximately triangular and thus the area of both can be obtained from their length and width L × W 2 However as the configuration of the loops may be extremely vague this method must be regarded as too inaccurate The area is best determined planimetrically or in the absence of a planimetre e.g. by calculating on graph paper the small squares that remain inside the loop. In addition to the area of the loop, it is of course possible to determine the areas of its parts, such as the area distribution in the various spatial directions or the area swept by the vector as a function of time [5]

The ratio between the anterior and posterior part of the area of the QRS loop gives a general idea of the loca- tion of the loop in the anteroposterior direction [144] It is naturally possible in the other directions to divide the loop into two parts on either side of a certain plane i.e to determine the relationships left right or superior/in ferior The locations of the extreme anterior and posterior points and the ratio of their distances from the ground line have been determined in a cor responding way By connecting mean extreme points Paul *et al.* reconstruc ted vectorial loops which may be con- sidered to represent some kind of mean loops for the groups in ques- tion [163] Configuration types are often described simply as narrow oval, round and figure-of-eight loops. It is also important, of course to state the direction of inscription. This is most important in the horizontal projection

since it is decisive in the diagnosis of hypertrophy of the right heart (see p. 30)

A very commonly applied method is to describe separately typical parts of the loop. They are the initial portion, body and terminal appendage. They are easy to distinguish in nearly every QRS loop. The initial portion and the terminal appendage are also indicated by the *initial* and *terminal inflection points*. The loop may be divided into more parts for analysis, e.g. into four components: initial, early, late and terminal, the boundary between the two midmost portions being 0.04 seconds [70]

The inscription speed of the different portions of the QRSaÊ loop is readily observable as the time orientation is distinct, the line being broken 400 times per second. This is of primary importance in bundle branch blocks. Terminal delay in such a case is diagnostic.

A general idea of the orientation of the loop can also be obtained from the common practice of announcing the octant or quadrant within which the greatest part of it is located [130, 131] or also the sextant [53] if only a projection on a certain plane is meant.

A very practical mode of representing spatial vectors and loops for analysis is to present them on a spherical surface [19]. The points at which the vector axes intersect the spherical surface are marked with spots of varying size, the radius of which is directly proportional to the magnitude of the vector in question. The loop can thus be depicted by marking a number of instantaneous vectors. As the QRSaÊ loop is on roughly the same plane, an arrow may be drawn on the spherical surface to show the orientation, slope and rotation of this plane. According to Brinberg [19] a loop can thus be denoted e.g. as follows: 45 7 *NE 30*. This means *that the mean vector axis of* the loop in question is on the spherical surface at 45 degrees longitude and 7 degrees latitude and that the body of the loop is travelling north-easterly and forms an angle of 30 degrees with the meridian of its position, which in this case is the 45 degree meridian [19]. Although terms such as longitude, latitude and the points of the compass are not very commonly used in vectorcardiography, they are very clear and useful when the sphere is used as the frame of reference.

Although the QRSaÊ loop is in fact on roughly one and the same plane some of its parts deviate from this plane to a greater or lesser extent. The magnitude of these deviations is illustrated by the tortuosity. It is determined by placing a movable meridian on the plane of QRS on the spherical surface and measuring the maximum deviation of the QRSaÊ loop from this plane to both sides. Tortuosity is then the sum of both these deviations in terms of degrees. The tortuosity of the loop portions can be determined in the same way [19]

Electronic computers have often been employed recently to analyse electrocardiographic and vectorcardiographic findings. The subject has been discussed by Pipberger *et al.* [176, 179] among others.

DIAGNOSTIC POSSIBILITIES OF VECTORCARDIOGRAPHY

The diagnostic possibilities of vectorcardiography are regarded as distinctly superior to those of scalar electrocardiography in some areas. This is apparent from even a brief review of the literature.

Hypertrophy of the right heart (RVH) can sometimes be manifested very untypically in Ecg, and Vcg is necessary to establish the diagnosis [128, 129 130]. According to Elek *et al.* who reported on 34 cases, Vcg is correlated better than scalar Ecg with the work of the right heart [53]. Richman and Wolff demonstrated easily interpretable changes in the Vcg of patients with congenital heart disease who had RVH [184]. In the material of Massie and Walsh, which includes 25 patients with isolated pulmonary stenosis, scalar Ecg displayed signs of right ventricular hypertrophy in about two-thirds of the cases whereas Vcg revealed them in all the cases [146]. In the same authors material of 239 patients with secundum type ASD scalar Ecg revealed hypertrophy of the right heart in c. 30 per cent and Vcg in 95 per cent of the cases [146]. A reliable vectorcardiographic diagnosis of RVH is very important also for evaluation of operative results and, furthermore, reduces the need for repeated catheterisation [80]. Vcg has also been held to be a suitable method for assessing the severity of pulmonary stenosis [207 247] and as an indicator of RVH in patients who have pulmonary stenosis with or without a ventricular septal defect [103].

Physiologic RVH of the newborn is often impossible to distinguish from pathologic RVH without the aid of Vcg. An indication of pathologic RVH in the Vcg is the clockwise direction of inscription of the horizontal QRS loop as late as the age of 1—4 months [35, 52, 60, 80, 158, 188, 225].

Hypertrophy of the left heart (LVH) can also be established more reliably by Vcg than by scalar Ecg. Astvatsatrian examined 100 children with active rheumatic carditis and found that incipient LVH was revealed earlier by Vcg than by scalar Ecg [11]. The same finding was made by Massie and Walsh for mitral stenosis in 435 patients [146]. Eleven of 95 patients with congenital aortic stenosis had a normal scalar Ecg, but the Vcg revealed distinct signs of LVH in all but one of these cases [104]. Marini found that LVH was revealed better by Vcg than by scalar Ecg in 52 children with congenital aortic stenosis or rheumatic mitral insufficiency [145]. The Vcg finding has also been regarded as a very suitable criterion for following the disappearance of LVH after ductus arteriosus persistens surgery [194].

Donoso *et al.* discussed Vcg findings in both right and left ventricular hypertrophies and recorded typical findings [43]. The Vcg, Ecg and autopsy findings for 167 patients were compared by Wolff *et al.*, who were studying the possibilities of Vcg and scalar Ecg in the diagnosis of hypertrophy and they found Vcg to be essentially superior [245].

Vcg offers better chances than ordinary Ecg of demonstrating *combined hypertrophy* [48]. In cases of combined hypertrophy in infancy Elliott *et al.* established in the Vcg three different types which help in diagnosis that is sometimes difficult with ordinary electrocardiography [56]. The direction of inscription of the horizontal projection of the QRSsE loop is counter-clockwise in two types and forms a figure-of-eight in the third.

Vectorcardiographic findings in hypertrophies of ventricles have been extensively studied in very recent papers, too, and a good correlation has generally been established, although comparisons with scalar Ecg have usually been omitted since Vcg is now generally considered to give unquestionably superior results [36, 59 102, 103, 118, 122, 123, 133, 137 223, 230, 243].

Bundle branch blocks are elicited more reliably by Vcg than by scalar Ecg, especially partial bundle branch blocks. This was established for left bundle branch block [LBBB] by Pantridge et al. [161] and Scherlis and Grishman [205]. Richman and Wolff drew attention to the diagnostic difficulties that arise when right bundle branch block

[RBBB] imitates LBBB. If such cases are assessed according to Wilson criteria from ordinary Ecg curves, the two blocks are concomitant. The reason may be an especially vertical position of the heart or an infarction. Vcg gave better information in these cases than scalar Ecg. Most important from the diagnostic standpoint in such cases are the initial vectors. [183] Grishman pointed out the difficulty of distinguishing partial LBBB and RBBB from physiologic terminal delay and stated that Vcg helps in such cases to arrive at reliable diagnosis [78]

Lamer et al. analysed by means of Vcg the RSR' complex of scalar Ecg in right chest leads and reported that with Vcg it is easy to distinguish between RVH and RBBB [137] It was emphasized by Lamer and Grishman that diagnosis of LVH or myocardial disease is difficult if there is coincident right bundle branch block which causes deviation of the TsE loop to the left. However the configuration of the QRSsE loop in Vcg helps to give the correct diagnosis [131] Lamer and Grishman noted that Vcg makes it possible to differentiate between RVH and RBBB and Ecg changes caused by marked rotation of the heart [129, 130, 131]. Burch and DePasquale also emphasized the unreliability of scalar Ecg in the diagnosis of RBBB and obtained more reliable results by means of Vcg [21, 22]. Penaloza et al. [171] and Gamboa et al. [71] induced transient bundle branch block in the human heart by applying pressure to the interventricular septum. Their most important observation was that the QRS interval is not the only criterion in the diagnosis of bundle branch blocks; the morphology of the QRSsE loop is more important. The delay of the terminal appendage of the QRSsE loop may be completely absent in mild RBBB and the QRS interval may thus be normal in the Ecg. Eguchi et al. arrived at the same conclusion [50]. Consequently the earlier view that the rSR' pattern in lead V is suggestive of RVH alone without RBBB if the QRS interval is short can no longer be considered reliable.

In atrial septal defect of primum type Vcg yields highly characteristic finding [16, 22, 128, 143, 172] There are fairly typical Vcg findings in many other congenital heart defects, but the primum type ASD is the best example. Vectorcardiography has been employed widely to study also ventricular septal defects. Two very recent reports may be mentioned. The Vcg finding displayed a better correlation with hemodynamic changes than scalar Ecg in cases with ventricular septal defect [162] In 100 patients with ventricular septal defect a significant statistical correlation between the increased magnitude of the initial and maximum QRS vectorial forces and the degree of left-to-right shunt was established [115] The literature concerned with Vcg findings in connection with various congenital heart defects is already voluminous. Garcia-Palmieri et al. made a good summary of this subject [72]

Vectorcardiography is considered to be superior to scalar electrocardiography in myocardial infarction diagnosis. Findings have been presented in very many studies [23, 34, 112, 122, 148, 153, 205, 233, 242, 244]

Some authors have warned against exaggerating the diagnostic possibilities of Vcg [217] The necessity for epicardial, intracardial and esophageal leads to obtain more information than is given by electrodes placed on the skin surface has also been pointed out [124, 125] It must always be remembered that Ecg and Vcg are not alternative or competitive methods of studying the electrical activity of the heart; they must be employed parallelly Both of them have their own specific spheres of application.

In addition to actual vectorcardiographic diagnosis, the value of the vectorcardiographic method is that the experience it gives makes it easier to interpret an ordinary electrocardiogram and helps in understanding the origin and role of the changes seen in it. Vectorial thinking in the practical interpretation of ordinary scalar Ecg has been stressed especially by Jouve and Buisson [111].

DIAGNOSTIC POSSIBILITIES OF VECTORCARDIOGRAPHY

The diagnostic possibilities of vectorcardiography are regarded as distinctly superior to those of scalar electrocardiography *in some areas*. This is apparent from even a brief review of the literature.

Hypertrophy of the right heart (RVH) can sometimes be manifested very untypically in Ecg, and Vcg is necessary to establish the diagnosis [128 129 130]. According to Elek et al. who reported on 34 cases, Vcg is correlated better than scalar Ecg with the work of the right heart [53]. Richman and Wolff demonstrated easily interpretable changes in the Vcg of patients with congenital heart disease who had RVH [184]. In the material of Massie and Walsh, which includes 25 patients with isolated pulmonary stenosis, scalar Ecg displayed signs of right ventricular hypertrophy in about two-thirds of the cases whereas Vcg revealed them in all the cases [146]. In the same authors material of 239 patients with secundum type ASD scalar Ecg revealed hypertrophy of the right heart in c. 30 per cent and Vcg in 95 per cent of the cases [148]. A reliable vectorcardiographic diagnosis of RVH is very important also for evaluation of operative results and, furthermore, reduces the need for repeated catheterisation [80]. Vcg has also been held to be a suitable method for assessing the severity of pulmonary stenosis [207 247] and as an indicator of RVH in patients who have pulmonary stenosis with or without a ventricular septal defect [103].

Physiologic RVH of the newborn is often impossible to distinguish from pathologic RVH without the aid of Vcg. An indication of pathologic RVH in the Vcg is the clockwise direction of inscription of the horizontal QRS loop as late as the age of 1—4 months [35, 52, 60, 80, 156, 168, 225].

Hypertrophy of the left heart (LVH) can also be established more reliably by Vcg than by scalar Ecg. Astvatsatrian examined 100 children with active rheumatic carditis and found that incipient LVH was revealed earlier by Vcg than by scalar Ecg [11]. The same finding was made by Massie and Walsh for mitral stenosis in 435 patients [146]. Eleven of 95 patients with congenital aortic stenosis had a normal scalar Ecg, but the Vcg revealed distinct signs of LVH in all but one of these cases [104]. Marini found that LVH was revealed better by Vcg than by scalar Ecg in 52 children with congenital aortic stenosis or rheumatic mitral insufficiency [145]. The Vcg finding has also been regarded as a very suitable criterion for following the disappearance of LVH after ductus arteriosus persistens surgery [194].

Donoso et al. discussed Vcg findings in both right and left ventricular hypertrophies and recorded typical findings [43]. The Vcg, Ecg and autopsy findings for 167 patients were compared by Wolff et al., who were studying the possibilities of Vcg and scalar Ecg in the diagnosis of hypertrophy and they found Vcg to be essentially superior [245].

Vcg offers better chances than ordinary Ecg of demonstrating *combined hypertrophy* [46]. In cases of combined hypertrophy in infancy Elliott et al. established in the Vcg three different types which help in diagnosis that is sometimes difficult with ordinary electrocardiography [56]. The direction of inscription of the horizontal projection of the QRSaŝ loop is counter-clockwise in two types and forms a *figure-of-eight* in the third.

Vectorcardiographic findings in hypertrophies of ventricles have been extensively studied in very recent papers, too, and a good correlation has generally been established, although comparisons with scalar Ecg have usually been omitted since Vcg is now generally considered to give unquestionably superior results [36, 50 102, 103, 118, 122, 123, 133, 137 223, 230 243].

Bundle branch blocks are elicited more reliably by Vcg than by scalar Ecg, especially partial bundle branch blocks. This was established for left bundle branch block [LBBB] by Pantridge et a. [161] and Scherlis and Grishman [205]. Richman and Wolff drew attention to the diagnostic difficulties that arise when right bundle branch block

so, the type of murmur c) any other abnormal cardiac finding. In suspicious cases it was advised that the child should be taken to the cardiac outpatient department for examination. A reply was obtained in almost all the cases and only a few children had to be omitted from the material for lack of an answer. These measures were considered sufficient to prevent children with congenital heart disease from being included in the present series.

The children included in the material had no other known diseases that could affect cardiac function. On the other hand, they had diseases and symptoms such as dislocation of the hip, clubfoot, hydrocephalus, microcephalus, hemorrhagic disease, jaundice of varying etiology, symptoms of mild brain damage, suspicion of neonatal infection, congenital laryngeal stridor, vomiting, conjunctivitis, Pierre—Robin syndrome, status Bonnevie—Ullrich, cleft palate, cephalhematoma, torticollis and Erb's paresis. As regards jaundice and hemorrhagic disease, manifestly anemic patients were not included in the series. The prematures were generally hospitalised on account of their prematurity.

The recordings were done at the Children's Hospital of University of Turku, the Department of Pediatrics of University of Oulu and at the Obstetric Department of Abolands

3

PRESENT INVESTIGATION

MATERIAL AND METHOD

MATERIAL

The material consisted of 250 healthy newborn infants aged a few minutes to 28 days. Ninety of them were premature and 160 were born at term. The distribution of the birth weights is given in Table 1 Several records were usually made from the same infant, using one or several lead systems. Frank s system was the prin cipal method used, and thus a suffi cient number of records was obtained to analyse the development of the Vcg finding during the neonatal period. Recordings by the other systems were confined to a few age groups and the results were compared with those obtained by Frank s method. A total of 360 recordings were made by Frank s method. Their distribution into age groups is given in Table 2 which also shows the number of recordings performed by other methods and their age distribution. The total number of recordings was 569

Table 1 Birth weights of the infants.

Birth weight	Number of infants
1000 — 1500 g	14
1500 — 2000	33
2000 — 2500	43
2500 — 3000	30

3500 — 4000	44
4000 — 4500	28
4500 — 5000	6
Total	250

All the full term newborn were in good condition at birth and at the time of the recording. Their Apgar score at the age of 1 minute was 7—10 The prematures, especially the smallest, included newborn with a lower Apgar score and newborn who were weak but not actually asphyxiated at the time of the recording. Small prematures were in an incubator during the recording. None of the newborn studied had anything suggestive of heart disease in their history routine Ecg, auscultation finding or other clinical status. If there was the least suspicion, a chest roentgenogram was taken. As not all congenital heart defects show symptoms in the neonatal period, a questionnaire was sent to the mother of each child before he/she was a year old. The mother was asked to take the questionnaire with her to the child welfare centre for the more thorough examination performed at the age of one The welfare centre physician who made the examination filled in the question naire and returned it to the author The questionnaire covered the following points. a) whether a heart mur mur was heard on auscultation, b) if

As regards jaundice and hemorrhagic disease, manifestly anemic patients were not included in the series. The prematures were generally hospitalized on account of their prematurity

The recordings were done at the Children s Hospital of University of Turku, the Department of Pediatrics of University of Oulu and at the Obstetric Department of Abolands

Sjukhus, Turku (a hospital owned by an association of communes) in 1963—1966. The following information was entered on cards for every patient.

1. Personal data, 2. Birth weight, birth length, head circumference and chest circumference immediately after birth 3. Age and weight at the time of recording, 4 Diagnosis, 5 History 6. Status, 7 Therapy 8. Mother's age and health 9 Course of the pregnancy 10 Course of the delivery 11. Apgar score 12. Data on siblings, 13 Familial diseases, 14. Anything else of note

None of the children in the series had received digitalis, sedatives or stimulants, corticosteroids or other drugs which might influence the function of the heart. During recording, the body temperature and the heart rate of every infant were within normal limits.

Most of the records were made halfway between meal times. Recording immediately before a meal is technically difficult on account of the restlessness of the infant. The infant is usually quiet on a full stomach, but the heart then lies slightly more horizontally than normal, which causes some deviation of the electrical axis of the heart to the left, at least in prematures [108] If the child was restless during the registration, he was given some time to settle and, if necessary an empty teat to suck. Sucking has an elevating effect on blood pressure from the second day of life in both full term infants and prematures [85 106] This, however is a finding that has been made on feeding the baby It is probable that sucking an empty comforter for pleasure when the child is not particularly hungry does not raise the blood pressure to the same extent. This possibility was considered by following the Vcg oscilloscopically before and after the baby was given the comforter and no difference was established.

APPARATUS

The electrocardiograph used for the recording was a two-channel Mingograph 24, made by Elema, Sweden. Both channels were connected to a two-channel oscilloscope Atlas Sichtgerät, made by Atlas, Germany The loops were photographed by a camera fixed at a standard distance from the tube The resistance-combining networks needed in Frank's and McFee's systems were prepared in the laboratory of the Cardiorespiratory Research Unit of Turku University Specially constructed electrodes, 1.0 cm in diameter were used and for the conductors thin, flexible hearing-aid wire. The electrodes were attached with breathing adhesive the electrodes around the thorax at the same level in Frank's system were fixed in position with a rubber belt. The large-sized electrodes used in Helm's system were made of rubber sponge and covered by rubber on the outer surface They were in five sizes, length of side 4.5—7.5 cm as it is important that the electrode size is in proper ratio to the patient's size. A broad rubber belt was used to fix these electrodes.

RECORDING TECHNIQUE

Vectorcardiographic recording is fairly sensitive to disturbances. Compared with ordinary electrocardiography this is because of the greater complexity of the method and the use of a five times greater amplitude which naturally amplifies the disturbances in the same ratio.

Newborn are exceptionally difficult examination objects for two reasons. Firstly the complete absence of co-operation and ready irritability on being woken and handled may make recording almost impossible in some cases. Secondly the skin resistance of the newborn is typically high. Measured between two electrodes the resistance varied from 50 K Ω to several thousand K Ω. High skin resistance places especially great requirements on the attachment of the electrodes. If the subject moves a good deal during the investigation it makes proper attachment still more difficult. In order to reduce skin resistance the infant's skin was wiped with a fatty solvent, usually an ether alcohol, before applying the electrodes. The resistance between the electrodes was the same when the electrode was applied as such to cleansed skin which had been moistened with physiological saline and when electrode paste or liquid was used. Mere physiological saline naturally dried more quickly. This was overcome by placing between the electrode and the skin a piece of blotting paper of the same diameter as the electrode, dipped in physiological saline. This method was employed in almost all the recordings; Elema's electrode paste was used in some. The inter electrode resistance was measured routinely. If the electrode-skin contact was faulty — an electrode often worked loose when the infant was restless — it was generally seen as an alternating current interference, or sometimes as a change in the loop configuration. It was sometimes difficult to eliminate an alternating current interference when recording in an incubator. For this reason, a Faraday cage with the dimensions of the incubator was made. Together with effective earthing it was sufficient on the whole to eliminate the disturbance. The disturbance eliminator of the electrocardiograph naturally cannot be used in vectorcardiography as the loop configuration and size change. When the finding differed perceptibly from the normal type a second recording was done after a short interval. There were hardly ever any great differences from the first record, which proves that the positioning of the electrodes was sufficiently constant.

If the patient was restless it was usually necessary to photograph several loops before a faultless and typical loop was obtained. This often required a fairly long time. The direction of inscription and the configuration of the loop were noted for every recording to avoid errors. Although the direction of inscription can be read from the parts of the broken line being traced that are sharp-pointed towards the direction of movement, there is a possibility of error when the configuration in a projection is intricate or comprises several loops.

Sjukhus, Turku (a hospital owned by an association of communes) in 1963—1968. The following information was entered on cards for every patient

1 Personal data, 2 Birth weight, birth length, head circumference and chest circumference immediately after birth, 3 Age and weight at the time of recording 4. Diagnosis, 5. History 6 Status, 7 Therapy 8. Mother's age and health, 9 Course of the pregnancy 10 Course of the delivery 11. Apgar score 12. Data on siblings, 13 Familial diseases, 14 Anything else of note

by Simonson *et al.* [213] an arc-shaped protractor was used. When McFee's and Parungao's system was employed, the distances between the three precordial electrodes and that of the two electrodes in the left flank were reduced in relation to the patient's size (McFee and Parungao expressed the distances in centimetres for adults). It was generally not possible to make recordings by all five systems at the same time. One, two or three methods had to suffice and then the procedure was continued later. Five methods require too long a time when the subject is a newborn infant.

Frank's system proved to be obviously the best as the work progressed. It gave more uniform results, as will be seen later, and its practicalness made it slightly more advantageous than Helm's or McFee's and Parungao's systems. Accordingly it was later selected as the sole method. The collection of a large material by all five methods would have been pointless, in the author's opinion, in view of the enormous work that the recordings would require. All the recordings were performed and analysed by the author.

THE METHODS OF ANALYSIS OF THE RESULTS

The commonest targets of analysis in vectorcardiography were enumerated in the Review of the Literature (pages 25—29). The targets chosen for analysis in the present work were QRSsÊ half area vector, TsÊ half area vector, QRSsÊ polar vector, spatial QRS-T angle and 0.005 sec., 0.01 sec., 0.02 sec., 0.03 sec. and 0.04 sec. QRSsÊ instantaneous vectors. Models representing typical average QRS loops were drawn in each plane via the mean termini of the QRSsÊ instantaneous vectors.

Spatial QRSsÊ half area vector is not a fully absolute concept as the QRSsÊ loop is never completely in the so-called QRS plane. Using spatial rotation, it is possible to measure the half area vector of the projection of the QRSsÊ vector in this plane. This vector may be regarded as a spatial half area vector at least approximately. When the half area vector is determined without spatial rotation, the surface areas of the projections must be measured. But the half area vectors of different projections are by no means always *projections of the same vector*. Pipberger recommends *taking the temporal mean of the half* area vectors of all projections and *suggests* that vectors thus obtained be regarded as the projections of the spatial half area vector which corresponds to the true spatial mean vector [173]. This method is very inaccurate. It is much more accurate to determine the half area vector from the largest projection in its area. This was the method employed in the present study. The largest loop area is mostly in the sagittal projection, sometimes in the frontal projection, in the newborn. In the cases in which the area of the sagittal and frontal *projections* was roughly equal in size, *the half* area

For instance as the initial portion is sometimes traced counter-clockwise in the frontal projection, the direction of inscription is almost always ambiguous in the record because the initial loop is so small. Interpretation of the cardiograms is further complicated by the fact that the immediate vicinity of the 0 point is overexposed the luminous point lies in this area most of the exposure time since the PsE and TsE loops of the newborn are generally small and partly superimposed. In addition, the luminous point is immobile in the 0 point during the intervals between the inscription of the different loops. By drawing a sketch as accurate as possible while the loops are being recorded, and by comparing it with the cardiogram, it is possible to be sure that no errors originate in the direction of inscription and order of inscription of the different parts of complex loops.

Overexposure of the vicinity of the 0 point, to which reference was made above emerges much more clearly in an enlargement of the cardiogram than in the negative for the exposure margin of the former is only a fraction of that of the latter It was almost impossible to obtain decent records of Vcg loops in the enlargement. Consequently the following method was used With the negative in the projector an enlargement of the picture is projected onto white paper in a dark room. The recording is then drawn on the paper in conformity with the picture thrown by the projector and a simultaneous check is made against the sketch drawn at the time of recording It is possible in this way to obtain fully reliable, technically faultless and, thus, easily readable records even for the newborn. For each recording the calibration was also traced and drawn on paper in order to make the measurements reliable.

PsE loops were disregarded. They are the smallest and the most difficult to record. Consequently significant information is not often gained from them in the newborn.

Scalar curves were also made in each recording, using the same electrode placings. They may be indispensable in certain cases later to obtain a reliable idea of the result. They differed fairly often from the conventional Ecg curves of the same patients because the lead vectors are different.

LEAD SYSTEMS USED

In the early phase of the study five systems were used side by side Grishman s cube system [81] Wilson s tetrahedron system [238] Helm s system [91] McFee s and Parungao s system [150] and Frank s system [65] (pages 12—15) The last three are so-called corrected systems. With Frank s system, the thoracic electrodes were applied at the height of the 4th intercostal space since the infants were supine which is the general practice proven correct by e.g. Langner *et al.* [126] Aware of the great sensitiveness of the C electrode of Frank s system to localisation error which has also been shown experimentally since

by Simonson et al. [213] an arc-shaped protractor was used. When McFee's and Parungao's system was employed, the distances between the three precordial electrodes and that of the two electrodes in the left flank were reduced in relation to the patient's size (McFee and Parungao expressed the distances in centimetres for adults). It was generally not possible to make recordings by all five systems at the same time. One two or three methods had to suffice and then the procedure was continued later. Five methods require too long a time when the subject is a newborn infant.

Frank's system proved to be obviously the best as the work progressed. It gave more uniform results, as will be seen later and its practicalness made it slightly more advantageous than Helm's or McFee's and Parungao's systems. Accordingly it was later selected as the sole method. The collection of a large material by all five methods would have been pointless, in the author's opinion, in view of the enormous work that the recordings would require. All the recordings were performed and analysed by the author.

THE METHODS OF ANALYSIS OF THE RESULTS

The commonest targets of analysis in vectorcardiography were enumerated in the Review of the Literature (pages 25—29). The targets chosen for analysis in the present work were QRSaÊ half area vector TaÊ half area vector QRSaÊ polar vector spatial QRS-T angle and 0.005 sec., 0.01 sec., 0.02 sec., 0.03 sec. and 0.04 sec. QRSaÊ instantaneous vectors. Models representing typical average QRS loops were drawn in each plane via the mean termini of the QRSaÊ instantaneous vectors.

Spatial QRSaÊ half area vector is not a fully absolute concept as the QRSaÊ loop is never completely in the so-called QRS plane. Using spatial rotation, it is possible to measure the half area vector of the projection of the QRSaÊ vector in this plane. This vector may be regarded as a spatial half area vector at least approximately. When the half area vector is determined without spatial rotation, the surface areas of the projections must be measured. But the half area vectors of different projections are by no means always projections of the same vector. Pipberger recommends taking the temporal mean of the half area vectors of all projections and suggests that vectors thus obtained be regarded as the projections of the spatial half area vector which corresponds to the true spatial mean vector [173]. This method is very inaccurate. It is much more accurate to determine the half area vector from the largest projection in its area. This was the method employed in the present study. The largest loop area is mostly in the sagittal projection, sometimes in the frontal projection, in the newborn. In the cases in which the area of the sagittal and frontal projections was roughly equal in size, the half area

vectors of both were measured and their temporal mean was taken. The temporal values are then very close to one another or the same Once the timed vector in question has been determined the same timed vector is taken from other projections. They are the components of the spatial half area vector When a loop is much narrower in one projection than the others or is, say figure-of-eight in shape determination of its half area vector would not be of any use The determination of the spatial half area vector calls for careful delibera tion in special cases, e.g. if a part of the QRSsÊ loop deviates very much from the so-called QRS plane

The TsÊ loop is generally small and narrow and its *half area vector* is therefore visualised directly without measurement of the surface area. The newborn material included few cases with such a large TsÊ loop that it was advisable to measure the area of a projection planimetrically

A spatial resolver is generally used for the determination of *QRSsÊ polar vector* It makes it possible to examine a loop on its own plane and the spatial direction and length of the polar vector are readily revealed In the present work a simple method without a spatial resolver was used, as follows.

The directions of the spatial vectors are denoted by points on the surface of a sphere The projections of the instantaneous vectors on the planes are known. The spherical coordinates, azimuth and elevation, are determined by revolution [19] as shown in Fig. 5. All instantaneous vectors are marked by points on the spherical surface. A movable meridian is placed on them to determine the QRS plane The point determined by the axis of the polar vector on the spherical surface lies on the same degree of longitude as the lowest point of this mobile meridian and 90 degrees upwards of it. For control purposes, a movable meridian may also be placed perpendicularly to the above movable meridian and the point at which it intersects the above-mentioned longitudinal meridian can be fixed. The spherical coordinates of this point are noted.

The spatial direction of the polar vector has been determined in the above way Its length is directly proportional to the area of the spatial loop This has been calculated from the areas of the projections, which have been measured planimetrically

As mentioned earlier (page 27) there are several methods of determining the *spatial QRS T angle* In this study a very simple and accurate method was used. The spatial QRS-T angle is determined between the half area QRSsÊ and half area TsÊ vectors, since the half area vectors correspond best to the true mean vectors [173] Spatial half area vectors have already been determined for every loop. Their spherical coordinates are now determined by revolution and the axes of the vectors are marked by points on the surface

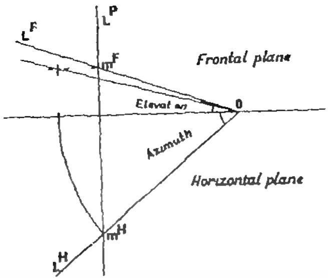

Fig. 6. Revolution when only the directions (L^F and L^H) of the vector projections are known. The azimuth is measured directly from the horizontal projection. An arbitrary perpendicular line (L^P) is plotted on the ground line some distance from the centre point O. Revolution is performed in the same way as in Fig. 5. by Om^F and Om^H, the parts of the projection lines bounded by the perpendicular line and the centre point.

of the sphere. The spatial angle between the QRSsÊ half area vector and TsÊ half area vector is then measured by a movable meridian. Brinberg's revolution method, described in Fig. 5 does not give an accurate determination of the spherical coordinates of TsÊ half area vector as the TsÊ loop is small. Vector lengths are of decisive importance in Brinberg's method, and thus the accuracy decreases when the vectors are small. In addition, it is sometimes difficult to make an accurate determination of the length of the TsÊ half area vector. Brinberg's revolution method was therefore modified in the present study: the vector lengths were dispensed with, and only their directions, the vector axes, were employed. An arbitrary perpendicular to the ground line was drawn to intersect their horizontal and frontal projections, and revolution was performed in the usual way by the segments of line bounded by this perpendicular and the 0 point (Fig. 6).

QRSsÊ instantaneous vectors were determined at intervals of 0.005—0.01 seconds. Since the loops are traced on the oscilloscope tube as a broken line — the breaks being 1/400 sec. — accurate temporal determination is possible. Instantaneous vectors are possible to determine at even shorter intervals if desired. The QRS interval was generally a little over 0.04 seconds, maximum 0.06 seconds, in the present material. A 0.04 second instantaneous vector was present in

practically all the QRSsE loops, but few QRS intervals were considerably longer than 0.05 seconds.

Reliable determination of QRSsE instantaneous vectors requires the combined examination of all their projections. The location of these vectors is often unclear from a single projection unless the examination is on the so-called QRS plane and even then difficulties may occur in many cases since some part of the loop may deviate appreciably from the plane. When a section of the loop runs perpendicularly to the plane temporal orientation at this site is impossible. When the path deviates considerably from the plane temporal orientation is difficult as the parts of the broken line are very short, especially if the inscription speed of the loop is slow in that section. An example of this is the 0 01 second vector which is often directed almost anteriorly It is then hardly possible to determine the frontal 0 01 second instantaneous QRS vector from a frontal projection alone On the other hand it is readily elicited by simultaneous examination of the sagittal projection, in which the 0 01 second instantaneous QRS vector is easy to determine The terminus of the frontal 0 01 second instantaneous QRS vector has naturally the same y component as the sagittal and is disclosed from the frontal projection by a point with the same y component. Similarly for each instantaneous vector it must be ensured that the projection of its terminus on every plane has roughly the same x, y and z coordinates.

STATISTICAL METHODS

There are certain difficulties involved in the statistical analysis of vectorcardiographic observations which do not occur in simple scalar quantities. Both vectorial and angular quantities have to be treated. The former are three-dimensional and have both direction and magnitude.

In the present work, the starting point of all the vectors was constant, the imaginary electrical centre of the heart. They can all be represented by *points determined by their termini in* the (x y z) coordinate system with its origo in the imaginary electrical centre of the heart. The projections of the points in question on the different planes, frontal, sagittal and horizontal, can be elicited in this way The spatial location of a point is established from its projections on two planes.

When analysing statistically a spatial vector group, its projections were always considered on two planes separately dealing with the x and y or y and z or z and x components of the points on each plane. As the standard deviation in the direction of two axes is hardly ever exactly the same the area of the standard deviation was drawn around the centre point as an ellipse with axes twice the length of the standard deviation parallel to both axes.

In the statistical treatment of angular quantities, Downs's method [46] which he and his co-workers recommended for vectorcardiography [47] and which was applied by Liebman *et al.* [139] for prematures, was not

used. This was because there was not in this material a deviation (range < 180 degrees) in angular quantities great enough to necessitate it.

Progressive changes occurred in some findings in the course of the investigation period. Regression analysis was planned, but the idea was abandoned because of the high number of different children in the various age groups. This was an inevitable consequence of the fact that a great proportion of the subjects were discharged from hospital during the investigation period and, also, the number in the youngest age groups was fairly small because of practical difficulties. In fact, the primary purpose was to investigate the possibility of applying the vectorcardiographic technique to the newborn and to establish normal findings for diagnostic use, rather than to follow the changes that occur during the neonatal period. Consequently these changes are presented in tabulated form or figures only giving the means and standard deviations.

For calculation of the arithmetic mean and the standard deviation, the sample was divided into classes, following the principle that the number of classes was to be the minimum of $^{2}\sqrt{n}$ where n refers to the total frequency of the sample.

The arithmetic mean was calculated from the following formula.

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{k} n_i x_i$$

and *the standard deviation* from the formula

$$S = \sqrt{\frac{1}{n-1} \sum_{i=1}^{k} n_i (x_i - \bar{x})^2}$$

where

k = the number of classes
n_i = the frequency of class i
x_i = the centre of class i

and *the standard error of the mean* from the formula

$$S\,(\bar{x}) = \frac{S_x}{\sqrt{n}}$$

To decide *the significance of the difference between two arithmetic means* ($\bar{x}$ and $\bar{y}$) the following computation was made.

$$t = \frac{\bar{x} - \bar{y}}{s\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}}$$

where

$$s = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}$$

where n_1 is the total frequency of x and n_2 that of y and s_1 is the standard deviation of x and s_2 the standard deviation of y. The t value thus obtained was compared with the values of Student's distribution table. If the risk (p) was

$0.01 < p < 0.05$	the difference between the means was called significant,
$0.0025 < p < 0.01$	the difference between the means was called highly significant,
$p < 0.0025$	the difference between the means was called very highly significant.

practically all the QRSsE loops, but few QRS intervals were considerably longer than 0 05 seconds.

Reliable *determination of QRSsE* instantaneous vectors requires the combined examination of all their *projections. The location of these* vectors is often unclear from a single projection unless the examination is on *the so-called QRS plane* and even then difficulties may occur in many cases since some part of the loop may deviate appreciably from the plane. When a section of the loop runs perpendicularly to the plane temporal orientation at *this site* is impossible. When the path deviates considerably from the plane temporal orientation is difficult as the parts of the broken line are very short, especially if the inscription speed of the loop is slow in that section. An example of this is the 0 01 second vector which is often directed almost anteriorly It is then hardly possible to determine the frontal 0 01 second instantaneous QRS vector from a frontal projection alone On the other hand, it is readily elicited by simultaneous examination of the sagittal projection, in which the 0 01 second instantaneous QRS vector is easy to determine The terminus of the frontal 0 01 second instantaneous QRS vector has naturally the same y component as the sagittal and is disclosed from the frontal projection by a point with the same y component. Similarly for each instantaneous vector it must be ensured that the projection of its terminus on every plane has roughly the same x, y and z coordinates.

STATISTICAL METHODS

There are certain difficulties involved in the statistical analysis of vectorcardiographic observations which do not occur in simple scalar quantities. Both vectorial and angular quantities have to be treated. The former are three-dimensional and have both direction and magnitude.

In the present work, the starting point of all the vectors was constant, *the imaginary electrical centre of the* heart. They can all be represented by points determined by their termini in *the (x, y z) coordinate system with* its origo in the imaginary electrical centre of the heart. The projections *of the points in question on the* different planes, frontal, sagittal and horizontal, can be elicited in this way *The spatial location of a point is* established from its projections on two planes.

When analysing statistically a spatial vector group its projections were always considered on two planes separately dealing with the x and y or y and z or z and x components of the points on each plane. As the standard deviation in the direction of two axes is hardly ever exactly the same, the area of the standard deviation was drawn around the centre point as an ellipse with axes twice the length of the standard deviation parallel to both axes.

In the statistical treatment of angular quantities, Downs's method [46] which he and his co-workers recommended for vectorcardiography [47] and which was applied by Liebman *et al.* [139] for prematures, was not

used. This was because there was not in this material a deviation (range < 180 degrees) in angular quantities great enough to necessitate it.

Progressive changes occurred in some findings in the course of the investigation period. Regression analysis was planned, but the idea was abandoned because of the high number of different children in the various age groups. This was an inevitable consequence of the fact that a great proportion of the subjects were discharged from hospital during the investigation period and, also the number in the youngest age groups was fairly small because of practical difficulties. In fact, the primary purpose was to investigate the possibility of applying the vectorcardiographic technique to the newborn and to establish normal findings for diagnostic use rather than to follow the changes that occur during the neonatal period. Consequently these changes are presented in tabulated form or figures only giving the means and standard deviations.

For calculation of the arithmetic mean and the standard deviation, the sample was divided into classes, following the principle that the number of classes was to be the minimum of $\sqrt{n}$ where n refers to the total frequency of the sample.

The arithmetic mean was calculated from the following formula

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{k} n_i x_i$$

and *the standard deviation* from the formula

$$S = \sqrt{\frac{1}{n-1} \sum_{i=1}^{k} n_i (x_i - \bar{x})^2}$$

where

k = the number of classes

x_i = the centre of class i

and the *standard error of the mean* from the formula

$$S\,(\bar{x}) = \frac{S}{\sqrt{n}}$$

To decide *the significance of the difference between two arithmetic means* ($\bar{x}$ and $\bar{y}$) the following computation was made

$$t = \frac{\bar{x} - \bar{y}}{s\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

where

$$s = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}$$

where n_1 *is* the total frequency of x and n_2 that of y and s_1 is the standard deviation of x and s_2 the standard deviation of y. The t value thus *obtained* was compared with the values of Student's distribution table. If the risk (p) was

$0.01 < p < 0.05$	the difference between the means was called significant,
$0.0025 < p < 0.01$	the difference between the means was called highly significant,
$p < 0.0025$	*the difference* between the means was called very *highly significant.*

RESULTS

FRANK'S SYSTEM

Spatial QRSsÊ half area vector

Spatial QRSsÊ half area vectors were determined temporally according to the half area vector of the projection that was largest in area. The results are given in Figs. 7—9 where the projections of the termini of the vectors are in the frontal and horizontal planes. Sagittal projections were not given as they can be seen from the above. The frontal and horizontal projections were chosen because if one wishes to determine the spherical coordinates they are usually constructed from the frontal and horizontal projections by revolution.

It can be seen from the results in the frontal plane that the QRSsÊ half area vector tends to turn progressively to the left with age. Thus, this occurs in the neonatal period already but only to full-term newborn. The QRSsÊ half area vectors of prematures in the youngest age groups are situated more to the left than in full term infants and no significant progression of the kind mentioned occurs in prematures. This difference between premature and full term newborn has been previously established in many studies for the electrical axis of ordinary Ecg [190 192, 224] and also for Vcg in 24-hour old infants [139]. Fig. 10 shows the changing of the transverse component of the QRSsÊ half area vector in full-term infants.

In the horizontal projections, a change to the anterior direction in the QRSsÊ half area vectors was observed after the first week of life. Here we have another significant difference between premature and full-term newborn. The vectors of the prematures aged less than two weeks were distinctly more anterior and the difference was significant, except on the first day. Full term newborn displayed more shifting of the vectors to the anterior direction, and from the age of two weeks this difference was no longer demonstrable. The author has reported earlier on the more anterior location of the QRSsÊ half area vectors of prematures [107]. The changing of the sagittal component of the vectors in full-term newborn is illustrated in Fig. 11.

When turning to the left and anterior the QRSsÊ half area vectors assumed an increasingly vertical direction and were consequently grouped in the horizontal projection within a fairly short radius around the II point from the age of two weeks.

Spatial TsÊ half area vector

For the spatial TsÊ half area vectors only the spatial direction was determined. This was because it is dif

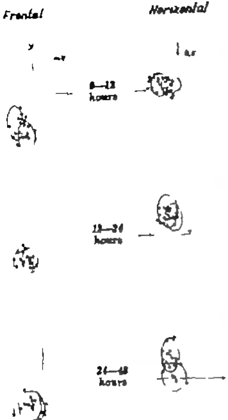

Fig. 7 Projections of the QRS&T half area vectors in the frontal and horizontal planes, age groups 0—12 hours, 12—24 hours and 24—48 hours. The solid dots indicate full-term infants and the circles prematures. The means of both are denoted by cross, for the latter in circle. The ellipse round both these crosses denotes the standard deviation in the direction of both axes.

ficult to determine their length accurately since they are fairly short and the measurement is complicated by the instability of the 0 point of the newborn and the over-exposure of its immediate environment in the photograph. In the newborn it is the orientation of the Taf loop that is of primary importance in practical analysis and diagnosis. The other properties of the T wave and also of the S-T segment are visualised better in an ordinary scalar Ecg.

The directions of the spatial Taf half area vectors are given in Fig. 12. Similarly to the QRSaf half area vectors, only their frontal and horizontal projections are entered in the figure. If required, the spherical coordinates can be determined from them by revolution (Fig. 8). The spherical coordinates have not been entered here as the plane projections are more important for practical analysis and diagnosis. Because of the definite skewness of the deviation of the findings, the arithmetic mean and standard deviation were not calculated. It seems that Taf half area vectors tend to assume a downward and slightly left

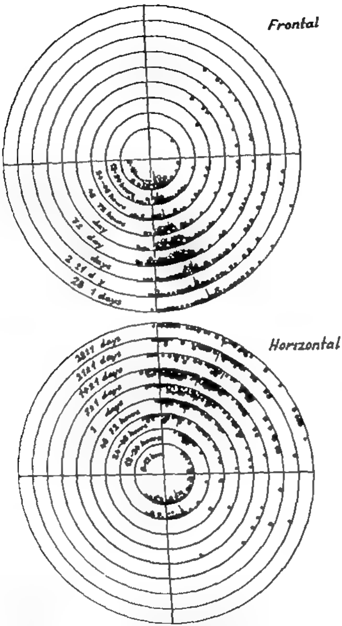

Fig 12 Directions of the frontal and horizontal projections of the Taft half area vectors. The solid dots indicate full term and the circles premature infants. The medians are marked by lines parallel to the radius.

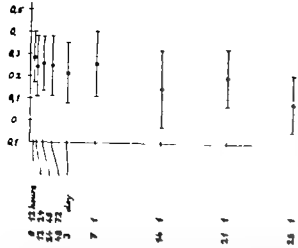

Fig. 10. Transverse components of the QRSsÊ half area vectors for full term infants according to age groups. The standard deviation on both sides of the mean is indicated.

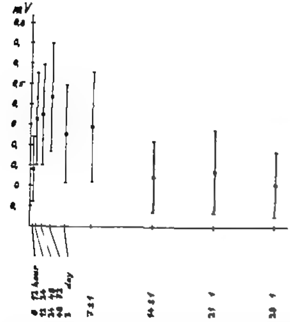

Fig. 11. Sagittal components of the QRSsÊ half area vectors for full term infants according to age groups. The standard deviation on both sides of the mean is indicated.

ward and posterior direction. Some of the vectors are directed sharply to the left, in some cases even slightly superiorly or anteriorly. On the other hand only a few vectors are directed to the right, and even those very slightly being located close to the centre of the clustering. As the arithmetic mean in such a case would lead to a false conclusion, a median was calculated for each age group. The medians were entered in the figure by lines parallel to the radius.

It can be seen from Fig. 12 that the direction of the TsÊ half area vectors gradually tends to shift to the left on moving to the older age groups, although the differences are not great. The typical changes in the first day of life emerge clearly. However all the vectors are then not located on the positive side of the axis of the conventional V_1 lead. Few recordings made during the first few minutes of the infant's life are included. Hait and Casul [84] reported that the TsÊ loop is then on the negative side of the axis of the V_1 lead and only afterwards assumes the typical first-day orientation. The same thing happened in the few infants of the present series for which a recording was made during the first minutes of life. However no concentration on the finding during these first minutes of the infant's life was made since it is not associated with the actual aim of this work and it is very difficult to get reliable Vcg recordings so rapidly. Conventional scalar Ecg is more suitable when the recording has to be performed in a couple of minutes.

No differences in the direction of the TsÊ vectors were established between premature and full-term newborn.

Table 5. Spatial QRS-T angles.

Age	Prematures		Full-term infants	
	Mean	SD	Mean	SD
0—12 hours	37.2°	27.0°	53.3	28.7°
12—24	50.7	25.2	56.8°	28.0°

21±1	38.1	22.4	42.5	17.1
28±1	37.2°	19.7°	35.8	12.6

planar QRS-T angles are not important (see p. 77) they were not determined at all. Because the dispersion of the values was not very great, the angles were treated as scalar quantities in the calculation of the means and standard deviations.

It has been established that the spatial QRS-T angle is widest in the neonatal period [12, 94] and that its deviation is greatest in the youngest infants [60]. The spatial QRS-T angles obtained in this study were distinctly smaller throughout than in the materials mentioned. A slight narrowing tendency seemed to appear in the course of the neonatal period, except that the angle was surprisingly small in prematures aged under 12 hours. However the dispersion was great in this group and such a limited number of cases does not warrant any conclusions. No significant parallel differences were seen between premature and full-term newborn, although the values for the prematures were higher in most age groups. The dispersion was also generally a little higher for the prematures.

QRSsÊ instantaneous vectors and configuration of the QRSsÊ loop

The 0.01, 0.02, 0.03 and 0.04 second instantaneous vectors were determined from all the recordings. The results are shown in *Figs.* 13—21. The 0.005 second initial vector was also determined and its *x* component is given in Fig. 22.

The means and standard deviations were calculated for the planar projections of the groups of spots formed by the termini of the instantaneous vectors. This was done by calculating them for the projections of these spots on the x, y z coordinates. Loops were drawn through the midpoints of the groups of spots. These loops run between the spots in the same way as on an average and can consequently be considered to represent the typical loops for the age groups in question.

Two progressive changes seen distinctly in these records occur during the neonatal period. Firstly there is a typical change *in the horizontal projection* from the fairly oval loops of the youngest age groups, with their clockwise direction of inscription, to slightly narrower loops which, in the typical cases, form a figure-of-eight where the direction of inscription of the anterior part is counter-clockwise. This development *resembles* in some degree that reported by Elek *et al.* [52] but differs considerably in that there were also posterior potentials in the present work. The types introduced by Elek and his co-workers had no posterior potentials, their loops were

QRSsÊ polar vector

The axes of the spherical coordinates determined for the QRSsÊ polar vectors are given in Table 3. The areas of the spatial QRSsÊ loops which decide the lengths of the polar vectors are listed in Table 4 where the value 1.0 is given to the median of the largest group infants aged 7±1 days. The arithmetic mean and standard deviation were not calculated here because they would give a false impression due to the skewness of the dispersion. When the axial directions of polar vectors are presented on a spherical surface, their lengths are directly proportional to the area of the spot displaying each vector.

Table 3. Spherical coordinates of the QRSsÊ polar vectors.

Age	Azimuth		Elevation	
	Mean	SD	Mean	SD
0—12 hours	—33.2	30.3	+20.3	23.3
12—24	—24.7	29.4	+24.4	28.9
24—48	—25.1	32.8	+20.2	20.8
48—72	—29.2	31.9	+19.3	21.8
3—4 days	—31.0	33.0	+16.9	30.2
7±1	—28.3	32.6*	+15.2*	28.3
14±1	—32.6	35.4	+13.7	26.7
21±1	—29.8*	33.5	+14.4	32.1
28±1	—27.2*	30.5	+10.0	24.0*

Table 4. Surface areas of the spatial QRSsÊ loops. *The value 1.00 has been given to the median of the 7±1 days age group, which is the largest one.*

	Median	Range
0—12 hours	1.25	0.48—3.45
12—24	1.22	0.45—3.12
24—48	1.15	0.41—3.23
48—72	1.13	0.21—3.33
3—4 days	0.97	0.24—3.28
7±1	1.00	0.21—3.40
14±1	1.18	0.29—3.36
21±1	1.21	0.19—2.98
28±1	1.38	0.25—3.31

No great progressive changes occurred with age in the direction of the polar vectors. The only significant change was the slight reduction in elevation of them during the neonatal period. The QRSsÊ loop then moves to a nearly vertical position. No definite differences were established between premature and full-term newborn.

The lengths of the polar vectors remained practically the same until the age of 3 weeks and was somewhat higher at 4 weeks (Table 4).

The polar vector cannot be determined with full exactitude because the QRSsÊ loop is not completely in the same plane and determination of this QRS plane is always a little uncertain. This difficulty is greater than usual in the newborn since the tortuosity is greater. In the present study the initial potentials deviated fairly noticeably from the QRS plane in nearly all the cases, but there were other fairly great deviations as well. It seems in fact that the polar vector is perhaps not quite as useful a quantity for characterising the loops for the newborn as it is later in life. But as increased tortuosity causes inaccuracy even in all the other objects of analysis, the polar vector deserves its place.

Spatial QRS-T angle

The magnitudes of the spatial QRS-T angle are given in Table 5. As the

great dispersion in the 0.02 and 0.03 second instantaneous vectors. This dispersion reveals, e.g., that the direction of inscription of the loop in the horizontal projection may be either clockwise or counter-clockwise in all the age groups, although the counter clockwise direction is rare in the youngest groups. The directions of inscription are listed in Table 6. Both directions, clockwise and counter clockwise as well as the figure-of eight, are seen in the horizontal projection in all age groups.

Another progressive change which is observed in the neonatal period occurs in the *0.005* second initial vector (Fig. 22). It deviates more to the right with age. The change is not great, it is true but it can be regarded as significant. Namin et al. [159] drew attention to the same phenomenon. The initial vectors are identical in full-term and premature newborn.

The change in the direction of the initial vectors is naturally connected with the direction of inscription of the horizontal projection. Initial vectors directed to the right cause the counter-clockwise direction of the anterior part of the loop.

Prematures and full-term newborn show the same *differences* that are seen more distinctly in the half area vectors, principally the slightly more anterior location of the 0.03 second vectors at the age of 1—4 days. The basic type of the loops, however is the same in both.

OTHER LEAD SYSTEMS

The significance of the differences between recordings made by different methods was studied in the following way.

Frank's system was used as the basis of the comparison. When a component showed a considerable difference on the average in the different systems, the difference between the successive recordings from the same child by these systems was established for the component in question. The mean, standard deviation and standard error of the mean of these differences were calculated. The results were then compared with 0 to establish the risk at which the difference could be claimed to exceed 0. The t-value of Student's distribution was calculated from the *formula*.

$$t = \frac{\bar{x}}{S(\bar{x})}$$

When the t value was compared with the values in Student's table the num-

OTHER LEAD SYSTEMS

The significance of the differences between recordings made by different methods was studied in the following way:

Frank's system was used as the basis of the comparison. When a component showed a considerable difference on the average in the different systems, the difference between the successive recordings from the same child by these systems was established for the component in question. The mean, standard deviation and standard error of the mean of these differences were calculated. The results were then compared with 0 to establish the risk at which the difference could be claimed to exceed 0. The t-value of Student's distribution was calculated from the *formula*.

$$t = \frac{\bar{X}}{S(\bar{X})}$$

When the t value was compared with the values in Student's table the num-

great dispersion in the 0.02 and 0.03 second instantaneous vectors. This dispersion reveals, e.g., that the direction of inscription of the loop in the horizontal projection may be either clockwise or counter-clockwise in all the age groups, although the counter clockwise direction is rare in the youngest groups. The directions of inscription are listed in Table 6. Both directions, clockwise and counter clockwise as well as the figure-of eight, are seen in the horizontal projection in all age groups.

Another progressive change which is bserved in the neonatal period occurs in the 0.005 second initial vector (Fig. 22) It deviates more to the right with age. The change is not great, it is true but it can be regarded as significant. Namin et al. [159] drew attention to the same phenomenon. The initial vectors are identical in full-term and premature newborn.

The change in the direction of the initial vectors is naturally connected with the direction of inscription of the horizontal projection. Initial vectors directed to the right cause the counter-clockwise direction of the anterior part of the loop.

Prematures and full-term newborn show the same differences that are seen more distinctly in the half area vectors, principally the slightly more anterior location of the 0.03 second vectors at the age of 1—4 days. The basic type of the loops, however is the same in both.

OTHER LEAD SYSTEMS

The significance of the differences between recordings made by different methods was studied in the following way·

Frank's system was used as the basis of the comparison. When a component showed a considerable difference on the average in the different systems, the difference between the successive recordings from the same child by these systems was established for the component in question. The mean, standard deviation and standard error of the mean of these differences were calculated. The results were then compared with 0 to establish the risk at which the difference could be claimed to exceed 0 The t value of Student's distribution was calculated from the formula.

$$t = \frac{\bar{X}}{S(\bar{X})}$$

When the t value was compared with the values in Student's table the num-

great dispersion in the 0 02 and 0 03 second instantaneous vectors. This dispersion reveals, e.g., that the direction of inscription of the loop in the horizontal projection may be either clockwise or counter-clockwise in all the age groups, although the counter clockwise direction *is* rare in the youngest groups. The directions of inscription are listed in Table 6 Both directions, clockwise and counter clockwise, as well as the figure-of *eight are seen in the horizontal projection* in all age groups.

Another progressive change which is observed in the neonatal period occurs in the *0.005 second initial vector* (Fig. 22) *It deviates* more to the right with age. The change is not great, it is true, but it can be regarded as significant. Namin et al. [159] drew attention to the same phenomenon. The initial vectors are identical in full-term and premature newborn.

The change in the direction of the initial vectors is naturally connected with the direction of inscription of the horizontal projection. Initial vectors directed to the right cause the counter-clockwise direction of the anterior part of the loop.

Prematures and full-term newborn show the same differences that are seen more distinctly in the half area vectors, principally the slightly more anterior location of the 0 03 second vectors at the age of 1—4 days. The basic type of the loops, however is the same in both.

OTHER LEAD SYSTEMS

The significance of the differences between recordings made by different methods was studied in the following way

Frank's system was used as the basis of the comparison. When a component showed a considerable dif ference on the average in the different systems, the difference between the successive recordings from the same child by these systems was established for the component in question. The mean, standard deviation and standard error of the mean of these differences were calculated. The results were then compared with 0 to establish the risk at which the difference could be claimed to exceed 0 The t value of Student's distribution was calculated from the formula.

$$t = \frac{\bar{X}}{S\ (\bar{X})}$$

When the t value was compared with the values in Student's table the *num-*

ber of degrees of freedom was n 1. Significance was denoted in the same way as elsewhere in this study (see p 41)

Grishman s cube system

Table 5 (page 33) shows the number and distribution into age groups of the recordings by this method. They were not performed on all the age groups because the primary object was to study the value of the system for the newborn.

For the same reason, only the QRSsÊ loop was examined. The QRSsÊ half area vectors and the maximal x, y and z components of the loops give the best idea of the differences from Frank s system. They are shown in Figs. 23 and 27 The most important differences from recordings made by Frank s system were

1. The spatial loops are smaller This is seen most distinctly in the frontal projection. The maximal x and y components are significantly smaller than in Frank s system.

2. The anterior potentials are markedly accentuated compared with other potentials. Some very weak posterior potentials are encountered, none at all in most recordings. There is a very highly significant difference between the cube system and Frank s in the antero-posterior ratio of the loop area in all the age groups. The difference between the sagittal components of the spatial half area vectors is also very highly significant. The same divergence between the cube system and Frank s system was noted by Massie and Walsh [146] and the preponderance of the right heart in the cube system compared with the other systems was observed by Rosen and Gardberg [188] and by Kimura and Toshima [117]

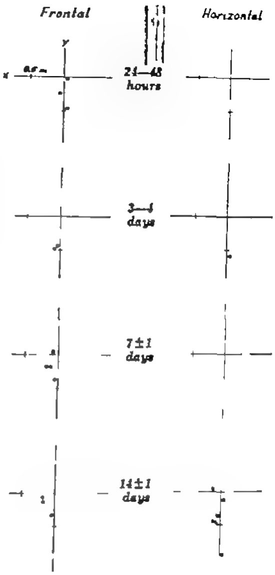

Fig. 23. Frontal and horizontal projections of the QRSsÊ half area vectors in recordings made by the cube system.

The dispersion in the recordings by the cube system was a little greater than in those by Frank s system.

There were no marked differences from Frank s system in the directions of inscription (Table 6)

There is no appreciable difference in practicalness between the two methods. The cube system is a little quicker because of its simplicity and the electrodes do not have to be posi tioned so accurately because not one is as close to the heart as the C electrode in Frank s system.

As far as interpretation is concerned, there is the disadvantage that the frontal projection is very small compared with the other systems. Frontal projection, however is often examined first as it is coordinated with the so-called standard leads of ordinary Ecg. Scalar Ecg taken by the same system also displays low amplitudes.

Wilson s tetrahedron system

Again, only the QRSaÊ loop was considered. The half area vectors are shown in Fig. 24 and the maximal x,y and z components in Fig. 27 Comparison with Frank s system showed the following differences:

1. The vertical component is heavily accentuated in the tetrahedron recordings. The spatial half area vectors are therefore located more inferiorly than in the recordings made by Frank s system, and the difference is significant in all the age groups, as it is between the maximal vertical components. This difference is due to the coefficients of the tetrahedron system. The coefficient of the vertical component is obviously too great. Frank also suggested this [61]

2. The loop is located significantly more anteriorly than in Frank s system but not as anteriorly as in the recordings made by the cube system.

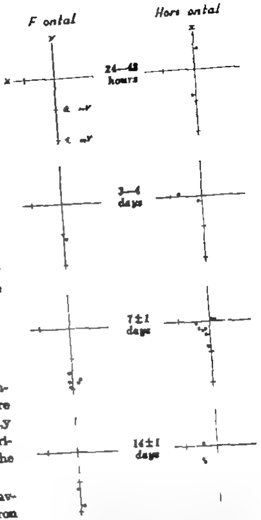

Fig. 24. Frontal and horizontal projections of the QRSaÊ half area vectors in recordings made by the tetrahedron system.

The dispersion was slightly greater with the tetrahedron than with Frank s system. There were no apprec iable differences in the directions of inscription (Table 6)

The tetrahedron system is the easiest of the systems used as regards

practicalness. The attachment of the electrodes to the limbs is easy and there are no difficulties of localisation. The dorsal electrode is the only one on the trunk. If an ordinary Ecg is made at the same time the same limb electrodes can be used The use of standardisation coefficients causes slight additional inconvenience since they must be adjusted separately for the different components. If the coeff icients were altered a little the tet rahedron system would compare better with the other systems for use in newborn and obviously also in larger children and adults.

Helm s system

The small number of recordings made by Helm s system gave the impression that it is not particularly suitable for use on the newborn. The half area vectors of the QRSaÊ loops are shown in Fig. 25, and the maximal x, y and z components in Fig. 27 Compared with the systems described above the following differ ences were noted

1. Helm s system greatly exagger ates the transverse potentials and the loops are therefore extremely wide in the frontal and horizontal projections. The difference from all the other systems used was very highly significant in this respect.

2 Some increase of the sagittal component compared with Frank s system was seen. It does not appear in the half area vectors, but the dif ference between the maximal sagittal components is highly significant (Fig. 27)

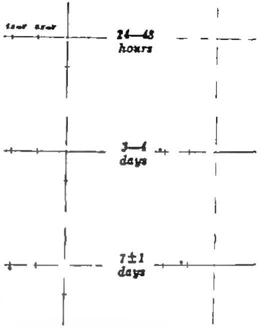

Fig. 25. Frontal and horizontal projections of the QRSaÊ half area vectors in recordings made by Helm s system.

The dispersion of the QRS half area vectors in the frontal and horizontal projections was greater than in the other systems, chiefly because of the accentuation of the transverse component, while the other components were roughly identical. This is why the dispersion of the instantaneous vectors is also unusually great. The lead vectors of the different components are obviously not of the same magnitude in the newborn with Helm s system. It is possible that the value of the method for use in the newborn could be improved by organising suitable resistances.

There were no appreciable differ ences from the other systems in the directions of inscription of the loops.

From the practical point of view too, Helm's system is not very suitable for studying newborn infants because its large sponge electrodes must be very accurately related to the size of the subject. This problem can be solved by having a series of suitable-sized electrodes for all newborn. The application of the electrodes takes a little more time than in Frank's system.

McFee's and Parungao's system

The half area vectors of the records made by McFee's and Parungao's system are presented in Fig. 28 and the maximal x, y and z components in Fig. 27. The half area vectors do not differ essentially from those of Frank's system. But there is a difference in the maximal sagittal component which is very highly significantly greater in McFee's and Parungao's system. However as the part of the loop located anteriorly is roughly as large as that located posteriorly in these age groups with both methods, the difference does not emerge in the half area vectors.

The dispersion with McFee's and Parungao's system was about the same as with Frank's system.

There were no appreciable differences from the other systems in the directions of inscription.

In the practical sense, the system of McFee and Parungao is not as good as Frank's because it requires more electrodes. The distances between the precordial electrodes and those on the left flank must be very

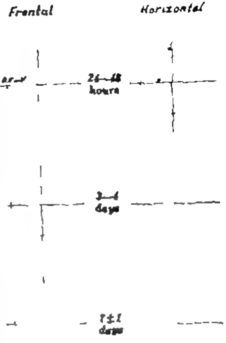

Fig. 28. Frontal and horizontal projections of the QRSaT half area vectors in recordings made by McFee's and Parungao's system.

carefully related to the size of the subject. If the infant is restless it is much more difficult to keep the electrodes in position.

Fig. 29 which shows recordings for a week-old full-term infant by all five systems, gives a good idea of the differences between the results of the systems used in this work. They were all made during the same day about midway between two meals, the first time by the cube and tetrahedron systems and the second time according to Frank, Helm, and McFee and Parungao.

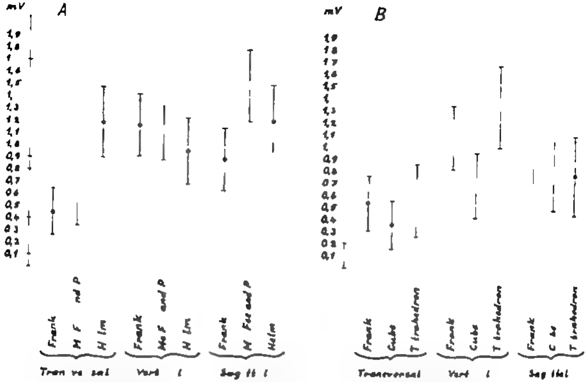

Fig. 27 The maximal components, parallel to the axes, of the QRSaE loops in recordings by different systems. The standard deviation on both sides of the mean is indicated. All the recordings in Fig. A were from the same infants, respectively and the same applies to Fig. B.

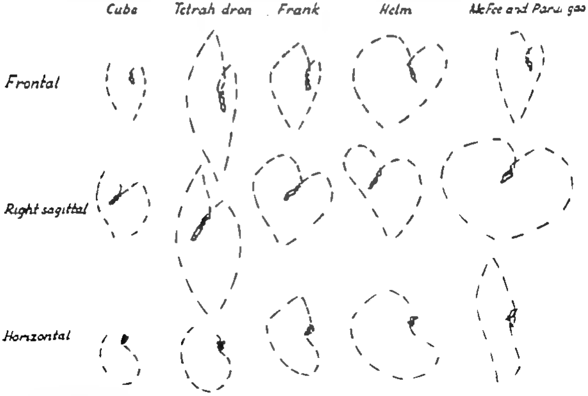

Fig. 28. Recordings from a week-old full term boy by all five systems. The typical differences between the systems are very distinct.

DISCUSSION

Since electrocardiography of the neonatal period has already been studied fairly extensively it is interesting to see whether the results of the present work really do provide new information concerning the electrical activity of the healthy heart in the neonatal period, elicited by vectorcardiography. If it does, the next problem is how far the findings are related to practical diagnostics. The latter aspect requires new studies using the same methods for both recording and analysis.

The findings selected for more detailed analysis here are such as cannot be obtained from scalar electrocardiograms. Everything that can be stated concerning them can therefore be said to add to our knowledge derived from ordinary electrocardiography. But, of course, much of the data is associated in some way with the findings given by electrocardiography.

QRSaE half area vectors are quantities characteristic of vectorcardiography. Although they have been compared with the mean vectors obtainable from scalar electrocardiogram [173] there is a very essential difference between them. Unlike all the quantities constructed from the surface areas of the waves of scalar Ecg, half area vectors are not a quantity integrated with time. Pipberger claimed that correct determination of the spatial half area vector and its projections takes one fairly close to a mean vector constructed from scalar Ecg [173] but this is valid only for normal recordings. For instance, terminal delay caused by bundle branch block does not change the location of the half area vector but affects essentially the mean vectors constructed from scalar Ecg. In contrast, the increase of terminal potentials to the right and upwards which occurs in e.g. hypertrophy of the right heart does not cause a major change in the mean vector constructed from scalar Ecg, unless accompanied by delay but does affect the half area vector very considerably.

The half area vectors determined in this study give an idea of the mutual relationship of the potentials of the different halves of the heart in the neonatal period and of the changes that occur in it during this period. It has been seen in many different connections that this relationship is revealed better by Vcg than by ordinary Ecg (see pp. 30—31). As was to be expected, the half area vectors are furthest to the right in the youngest age groups and this preponderance of the right heart decreases slightly already in the neonatal period. The difference between prematures and full-term newborn in this respect has

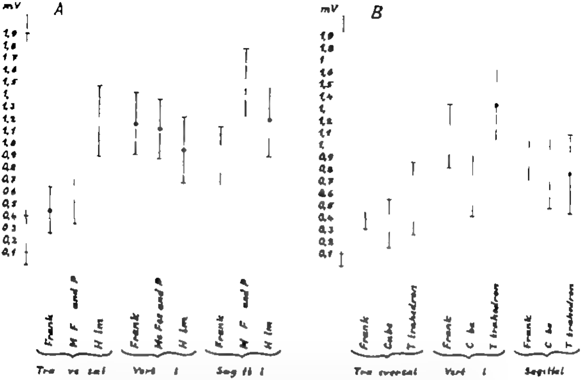

Fig. 27 The maximal components, parallel to the axes, of the QRSaß loops in recordings by different systems. The standard deviation on both sides of the mean is indicated. All the recordings in Fig. A were from the same infants, respectively and the same applies to Fig. B.

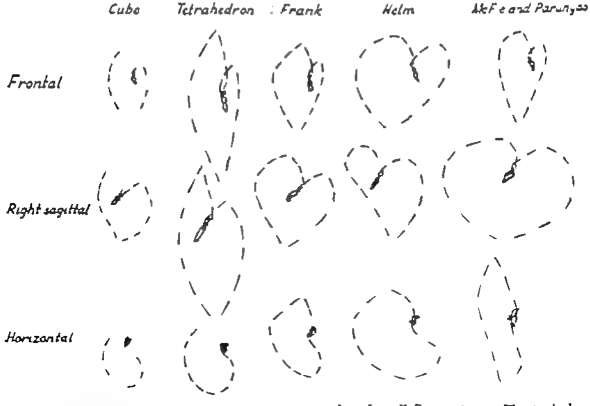

Fig. 28. Recordings from a week-old full term boy by all five systems. The typical differences between the systems are very distinct.

study or by a spatial rotator. However as we learn with practice to estimate the polar vector approximately from the loop projections, it can be employed in direct diagnosis once the normal value and dispersion for the age group in question is known.

Since the tortuosity of the QRSaE loop is great in the neonatal period, determination of the polar vector must always be slightly inaccurate. It is therefore possible that, in addition to the changes observed in elevation, minor changes may occur during the neonatal period also in the azimuth of the polar vector although the changes which occur in, say, the half area vectors need not necessarily be reflected in the polar vectors. The *present study gives the impression that the polar vector does not reflect quite so sensitively as the half area vector the small changes that occur in the relative strength of the different halves of the heart. On the other hand it is possible that also in the newborn, values outside the normal range indicate with all the more likelihood a pathologic cardiac finding.*

As far as the *QRS-T angle* is concerned, the importance of *spatial* determination must be emphasized. QRS-T angles have often been determined on different planes, but this can hardly be considered important. If the vectors that form the QRS-T angle deviate considerably from the plane in which their projections are examined, the size of the angle changes so much that every angle from 0 to 180 degrees may occur in the projection. Therefore, only the spatial QRS-T angles are presented in this study. Although they cannot be seen direct from the Vcg recordings, they can with a little practice be estimated roughly from the plane projections. Accurate determination can be performed rapidly by revolution and with a sphere.

The conclusion arrived at in this study is that the spatial QRS-T angle is not greater in the newborn than during later life. The values obtained for the different age groups are even a little smaller than the normal values recorded for adults [13]. Higher values have been reported for the newborn, according to Fowler 71 degrees, standard deviation 21 degrees [60]. Rothfeld *et al.* obtained considerably smaller values for QRS-T angles of the newborn in plane projections [189]. As the angles were fairly small on all planes, under 40 degrees in the majority of the cases, even the spatial QRS-T angles in their material could surely not have been very great.

There is in fact no reason why the spatial QRS-T angle of the newborn should be greater than it is later in life. When the preponderance of the right heart is physiologic in the newborn, there is no accompanying decrease in the concordance of QRS and T. *One criterion for distinguishing between pathologic and physiologic preponderance of the right heart may perhaps be the size of the spatial QRS-T angle in addition to the direction of inscription of the horizontal projection of the QRSaE loop* (see p. 30).

been established earlier by both ordinary Ecg [190 192, 224] and Vcg [139] The preponderance of the right heart is not as pronounced in prematures as it is in full-term newborn. According to the present study the half area vectors of premature and full term newborn in the frontal projection are approximately parallel from the age of two weeks. *The slighter preponderance of the right heart seen in prematures in the first 1—2 weeks of life* indicated by the conventional thorax leads as well, *is understandable because the relative strength of the different halves of the premature s heart in the first 1—2 weeks of life evidently corresponds still to the situation during the late fetal period* (see p 19)

More difficult to explain, on the other hand is the location of the half area vectors in the anteroposterior direction and the differences in this respect between prematures and full term newborn observed in this study Full term newborn reveal a shift in the anterior direction at the age of about one to two weeks, with Frank s method of recording, whereas the vectors of prematures are originally located more anteriorly — the difference is significant at the age of 1—7 days — and thus no notable changes occur in the neonatal period. The slight difference in the anatomic position of the heart between prematures and full term newborn is probably of significance in this respect.

The vectorcardiographic method is not as important for the *TsÊ half area vector* Owing to the small size of the TsÊ loop and its usually fairly narrow oval shape in the newborn, its half area vector is in practice very close to the maximal vector and mean vector The planimetrically determined half area vector is of importance here only when the TsÊ loop is broader than usual and thus larger in area or very irregular in shape.

The behaviour of T wave in the neonatal period has been studied extensively from scalar Ecg. Hait and Gasul [84] made a very detailed study of it from the very first moments of the infant s life albeit on a fairly small material. They called attention especially to spatial orientation. Although the results of the present study differ from theirs in that the TsÊ loops here are localised more inferiorly and posteriorly the difference is not of great importance in point of principle However it is not easy to obtain for the determination of the QRS-T angle a sufficiently accurate spatial orientation of the TsÊ loop from an ordinary Ecg. The value of the vectorcardiographic method is thus obvious here too.

The *QRSsÊ polar vector* is a typical vectorcardiographic quantity which cannot be constructed from an ordinary Ecg. Its diagnostic importance was stressed by Burger and Vaane [32] and Pipberger [175] It gives an idea of the location of the QRS plane and of the area of the spatial QRSsÊ loop. The polar vector is not so easy to establish from the projections of the QRSsÊ loop as the spatial half area vector it must be determined by revolution, as in the present

presented only in an orientating sense to facilitate the recognition of definitely normal recordings at first glance. There are great differences among normal recordings. The same components are usually not exactly of the same length in different projections. This is because every projection is recorded separately i.e. during a different contraction of the heart. If the recording system were complete and the electrical activity of the heart identical during the different contractions, the same component of the same magnitude would always be obtained independently of the projection. It is of course possible to make them all equal in size by recording all the projections simultaneously [79] or by measuring each component from only one projection and giving the corresponding component of the other projections similar values, as is sometimes done. The result, however does not then correspond to the true finding. The differences in the same component in different projections give some idea of the accuracy of the recording method, and presenting of the dispersion separately on all planes provides information on the variation of the findings on each plane separately.

The dispersion of the groups of spots, especially in the 0.02 and 0.03 second instantaneous vectors, shows that the loop configuration may change considerably. Rautaharju therefore called in question the significance of vector loop cardiography as a whole [160]. In certain cases, however the loop configuration also displays features which are highly diagnostic.

Paul *et al.* constructed typical loops from extreme vectors [163] but this method is somewhat incorrect for the reason mentioned above (p. 78). The results obtained by Paul *et al.* in their lowest age groups concur fairly well, nevertheless, with the results arrived at in the present study.

Taking the present results as a whole, it can be seen that the normal values for the neonatal period may be considered to be diagnostically significant values. Comparison with some other results obtained for the newborn shows that the dispersions are smaller in many respects in the present investigation. Since a fairly comprehensive material was studied by Frank's system, the statistical weight of the observations may be regarded as sufficient for diagnostic use. Technical experience in the performance of recordings and analysis of the results in studies of the newborn should be stressed.

Several lead systems can be used for vectorcardiographic study of the newborn. From experience in the present study Frank's system was found to be fairly serviceable. Owing to the special character of the subjects, it is hardly possible to adopt in clinical use methods that require very many electrodes. On the other hand, some factors that cause errors are especially strong in the newborn, e.g. specific anatomic characteristics, greater skin resistance restlessness, etc. Hence

The spatial QRS-T angle has a fairly considerable general importance in vectorcardiographic diagnosis. It is clear that the relations between the depolarisation and repolarisation of the ventricles of the heart are of great significance The ventricular gradient indicates the same relation. It is true that the ventricular gradient determined in the frontal plane the classical way is inaccurate and even during great changes in the T wave can remain within the normal range [181] The spatial ventricular gradient is a much better criterion [179] But if it is determined from conventional Ecg leads the inaccuracy is still considerable. *An accurately determined spatial QRS T angle using a corrected lead system for the Vcg recording obviously gives the best possible picture of the relationship between the depolarisation and repolarisation of the heart muscle*

QRSsÊ instantaneous vectors are very difficult to determine with absolute accuracy but reasonable accuracy can be achieved if the loop is traced as a broken line in the oscilloscope and the distance between the breaks in the line is fixed, e.g. 1/400 second. (The tecnique is described on p. 40) These instantaneous vectors are probably of considerable diagnostic importance. They can be used for temporal analysis of a certain part of the loop and for comparison of the differences in it between different subjects. Most other comparable quantities illustrate the loop in its entirety Another alternative is to compare so-called extreme vectors, but this method cannot be deemed reliable since an extreme vector of the same direction may be a vector of a completely different phase The extreme superior vector of the newborn may be e.g. an initial 0 005 second instantaneous vector or more often, a 0 035 second instantaneous vector and the extreme left vector may be similarly e.g. a 0 01 second or 0 04 second instantaneous vector etc. Their comparison thus cannot yield reliable results. The disadvantage of comparing instantaneous vectors, again, is that the vectors at the terminal part of the loop, such as the 0 04 second instantaneous vector in the newborn, are not associated in all subjects with the same electrical phase of the heart because the duration of the QRSsÊ loop varies. In most newborn this vector is associated with the extreme terminal phase of ventricular depolarisation. When, on the other hand the duration of ventricular depolarisation is as much as 0 05 or even 0 06 seconds, the 0 04 second instantaneous vector is then not associated with the terminal phase of depolarisation and, thus, is not comparable with the former However the majority of the newborn belong to the first mentioned group and the cases are comparable. Figs. 13—21 show that some of the 0 04 second instantaneous vectors are situated much more superiorly These are the instantaneous vectors of just those infants with a considerably longer than average duration of ventricular depolarisation.

The average types of the plane projections of the QRSsÊ loops are

SUMMARY

The purpose of the present study was to examine the value of the vectorcardiographic technique in the neonatal period, the technical requirements involved and the normal findings for newborn infants of different ages.

The material consisted of 250 newborn infants of whom 90 were premature. 360 Vcg recordings were performed on them by Frank's lead system. In addition, a smaller number of recordings were made by four other much used systems: Grishman's cube (72 recordings) Wilson's tetrahedron (72 recordings) Helm's (30 recordings) and McFee's and Parungao's (25 recordings).

In order to obtain normal values for newborn of different ages, recordings were performed for 9 age groups: 0—12 hours, 12—24 hours, 24—48 hours, 48—72 hours, 3—4 days, 7 ± 1 days, 14 ± 1 days, 21 ± 1 days, and 28 ± 1 days.

Special features of vectorcardiographic study of the newborn relating to the performance of the recordings and to analysis of the results are discussed.

The most important findings were

1. The vectorcardiographic technique lends itself well to use on the newborn. The dispersion of the results is generally no greater than later in life.

2. Frank's proved to be the most suitable of the lead systems used here for study of the newborn as regards practical clinical use and accuracy and reliability of the results.

3. The QRSsÊ half area vectors deviated to the right in the newborn in the same way *as the electrical axis* constructed from ordinary Ecg. In full-term newborn there was a gradual shift to the left and anteriorly during the neonatal period, after the first 1—2 days (Figs. 10—11).

4. The TsÊ half area vectors were mostly located posteriorly and inferiorly and gradually turned slightly to the left during the neonatal period (Fig. 12). An exception was the first day of the infant's life, most of the vectors being then anterior in direction.

5. The QRSsÊ polar vectors were directed to the left, slightly posteriorly and inferiorly. Azimuth averaged -24.7— 33.2 degrees in the different age groups and the corresponding elevation was +10.0 — +4.4 degrees (Table 3).

6. The spatial QRS-T angle was of the same magnitude in the neonatal period as later in life and the same was true of its dispersion. The means for the different age groups ranged from 35.5 to 61.0 degrees (Table 5).

7. The QRSsÊ instantaneous vectors were determined at 0.005 0.01,

corrected systems should be employed for clinical studies, too Of the corrected systems, Frank's combines in the author's opinion sufficient accuracy and practicalness and can consequently be recommended for routine use in the newborn. The other systems on the whole gave results that were so divergent that clinical recordings made by them could not be compared with the normal values obtained with Frank's system in this study

0 02 0 03 and 0 04 seconds. Mean QRS loops were drawn via the termini of the mean instantaneous vectors for the different planes (Figs. 13—21) Two progressive changes occurred in the instantaneous vectors during the neonatal period and they were visible also in the shape of mean loops. a) Typical development occurred in the horizontal projection from the fairly oval loops of the lower age groups with a clockwise direction of inscription, to slightly narrower loops forming a figure-of-eight pattern with counter-clockwise rotation of the anterior part. However the direction of inscription was still clockwise in many cases at the age of 28 days (Table 6) b) The 0 005 second initial vector was located anteriorly to the left in the lowest age groups and then turned gradually to the right (Fig 22)

8. The results of the other systems differed from Frank s system in the following respects a) The cube system exaggerated the anterior potentials while the other potentials were weak and the loops were fairly small. b) The tetrahedron system exaggerated the vertical component because the standardisation coefficient is too great for the newborn. The anterior potentials were slightly accentuated compared with Frank s system. c) Helm s system exaggerated the transverse component very sharply and the sagittal component in a small degree. d) McFee s and Parungao s system exaggerated the sagittal component sharply but the other components were similar to those in Frank s system. The differences between the various systems are illustrated in Figs. 27—28.

9 The most important of the differences between the prematures and full term newborn were

a) The QRSsE half area vectors of the prematures during the first week of life were localised less to the right, and thus preponderance of the right heart was not as distinct as in full-term newborn (Figs. 7—8)

b) At under 2 weeks of age the QRSsE half area vectors of the prematures were localised distinctly more anteriorly than those of full-term *infants, except on the first day (Figs. 7—8)*

c) The same differences that were observed in the QRSsE half area vectors were naturally visible also in the QRSsE instantaneous vectors, but not quite so clearly

The conclusion reached is that the vectorcardiographic method can be recommended for clinical routine use in cardiac study of the newborn. For the recording procedure Frank s system is recommended, and for this the normal values obtained in this study can be used.

CHAPTER I

Introduction and aim of the investigation

The different anatomical types of atrial septal defect were described by Rokitansky in 1875 and in 1916 Lutembacher presented the combination of atrial septal defect and mitral stenosis. But it was not until 1941 that Bedford et al. described the physical signs and the electrocardiographic and roentgenological findings in atrial septal defect as a clinical entity. In 1947 the first cardiac catheterization in atrial septal defect was performed by Cournand et al.

Surgical treatment of atrial septal defect of the secundum type was introduced during the 1950's by Bailey et al. (1952) Björk & Crafoord (1953) and Søndergaard (1954) among others, with different closed methods. The results of open heart surgery under hypothermia in atrial septal defect were described by Lewis and Taufic (1953) and Blount et al. (1954) and with the aid of extracorporeal circulation by Lillehei et al. (1955) among others. Since this period a large number of reports concerning investigations of atrial septal defects have been published.

Since several literature reviews on this subject ha e already been made, the reader is referred to the works of Reindell et al. (1962) Schrire and Vogelpoel (1964) Derra, Grosse-Brockhoff and Loogen (1965) and Zaver and Nadas (1965)

The clinical picture and cardiological findings in atrial septal defect of the secundum type have been fully described and may be assumed to be well known. For the literature on this subject and the results of previous investigations, reference may thus be made to Wood (1956) Symposium on Atrial Septal Defect (1958) Kjellberg, Mannheimer Rudhe and Jonsson (1959) and Davidsen (1960)

The natural history and prognosis in atrial septal defect of the secundum type has been greatly discussed. Roesler (1934) Burrett and White (1945) and Bedford et al. (1957) found a mean life expectancy of 36—39 years. Campbell et al. (1957) and also Wood (1962) found, however that the prognosis in uncomplicated atrial septal defect of the secundum type was relatively favourable up to the age of 40—50 years, and according to Wood the object is to prevent considerable morbidity between the ages of 50 and 60 and to prevent death between the ages of 60 and 70"

According to Adams (1965) a large left to-right shunt in atrial septal defect of the secundum type can be tolerated even up to the ages of 70—80 years. On the other hand, attacks of cardiac failure during the first year of life have been described by Nakamura and Nadas (1964) among others, and according to Kavanagh-Gray (1963) death may occur at this age.

CHAPTER I

Introduction and aim of the investigation

The different anatomical types of atrial septal defect were described by Rokitansky in 1875, and in 1916 Lutembacher presented the combination of atrial septal defect and mitral stenosis. But it was not until 1941 that Bedford et al. described the physical signs and the electrocardiographic and roentgenological findings in atrial septal defect as a clinical entity. In 1947 the first cardiac catheterization in atrial septal defect was performed by Cournand et al.

Surgical treatment of atrial septal defect of the secundum type was introduced during the 1950's by Bailey et al. (1952) Björk & Crafoord (1953) and Søndergaard (1954) among others, with different closed methods. The results of open heart surgery under hypothermia in atrial septal defect were described by Lewis and Taufic (1953) and Blount et al. (1954) and with the aid of extracorporeal circulation by Lillehei et al. (1955) among others. Since this period a large number of reports concerning investigations of atrial septal defects have been published.

Since several literature reviews on this subject have already been made, the reader is referred to the works of Reindell et al. (1962) Schrire and Vogelpoel (1964) Derra, Grosse Brockhoff and Loogen (1965) and Zaver and Nadas (1965)

The clinical picture and cardiological findings in atrial septal defect of the secundum type have been fully described and may be assumed to be well known. For the literature on this subject and the results of previous investigations, reference may thus be made to Wood (1956) Symposium on Atrial Septal Defect (1958) Kjellberg, Mannheimer Rudhe and Jonsson (1959) and Davidsen (1960)

The natural history and prognosis in atrial septal defect of the secundum type has been greatly discussed. Roesler (1934) Burrett and White (1945) and Bedford et al. (1957) found a mean life expectancy of 36—39 years. Campbell et al. (1957) and also Wood (1962) found, however that the prognosis in uncomplicated atrial septal defect of the secundum type was relatively favourable up to the age of 40—50 years, and according to Wood "the object is to prevent considerable morbidity between the ages of 50 and 60 and to prevent death between the ages of 60 and 70"

According to Adams (1965) a large left-to-right shunt in atrial septal defect of the secundum type can be tolerated even up to the ages of 70—80 years. On the other hand, attacks of cardiac failure during the first year of life have been described by Nakamura and Nadas (1964) among others, and according to Kavanagh-Gray (1963) death may occur at this age.

Since the long term prognosis in atrial septal defect of the secundum type, although difficult to assess, is not entirely favourable, and since the operation mortality is low Derra et al. (1965) conclude that in general, operation is indicated if the left to-right shunt is 30 per cent or more of the pulmonary blood flow A predominant right to-left shunt due to raised pulmonary resistance should constitute a definite contraindication to operation, as also should therapy resistant myocardial insufficiency

The *operation mortality in different* series of cases is always difficult to evaluate and varies amongst other things according to the selection of cases for surgery In an analysis made by the Committee on Cardiovascular Surgery American College of Chest Physicians (1963) a mortality of 3 per cent was reported in 397 patients operated on with different closed methods, while 542 patients had undergone operation under hypothermia, with 3 per cent mortality and 1206 patients operated on under extracorporeal circulation showed a mortality of 4 per cent.

In a series of 206 "good risk" patients with uncomplicated secundum defects subjected to operation under hypothermia, Sellors (1961) reported a total mortality of 0.5 per cent, and approximately the same result was obtained by Derra et al. (1965) with only two deaths among 215 such patients. Derra states that the total operation mortality in atrial septal defect of the secundum type is now probably lower than 2 per cent in most thoracic surgical centres. In view of the gradual reduction of the operation mortality in open repair of atrial septal defects of the secundum type, it is sometimes considered that the diagnosis in itself constitutes an indication for operation (Zimmerman 1958 Mustard 1961 Gasul et al. 1961) but other authors (Taussig 1960 Gross 1962 Wood 1962) are of the opinion that with small defects, which are usually compatible with a normal life operation is not usually indicated.

Partly owing to variations in the selection of patients and the operation technique, the operation results in different series of cases, *often expressed as the* mortality rate and the number of residual shunts, are difficult to compare. In one of the first investigations made after closed heart operations in atrial septal defect Kirklin et al. (1956) found 6 residual shunts in 20 recatheterized patients, among 32 operated on by the Gross method At the same time "a mild drop in pulmonary artery pressure even when it has been within the range of normal prior to operation" was shown.

Sondergaard (1962) found a functionally closed defect in all except one of 66 recatheterized patients in his own operation series, although the defect was completely closed in only 54 patients. Carlgren (1961) found small residual shunts in 9 of a smaller series of 24 patients operated on by the same method

Residual left to-right shunts have also been demonstrated after open repair of atrial septal defects. These have usually been of a lower frequency but varying figures of up to 20 per cent are reported. Bedford et al. (1957) investigated 40 patients after operation under hypothermia, including 12 with cardiac cathe

terization. A residual shunt was shown in 5 patients. Winchell and Bashour (1958) compared the haemodynamic conditions at rest before and after operation under hypothermia in 20 patients with atrial septal defect of the secundum type, and found a residual left-to-right shunt in only 1 patient, who was found at operation to have an undiscovered anomalous pulmonary vein opening into the superior vena cava. In summary these authors state that "closure of the atrial septal defect brought about the changes that one would anticipate such as reduction of pulmonary blood flow and pulmonary artery pressure to normal if it was initially elevated".

Among 65 patients with atrial septal defects of the secundum type, catheterized after operation under hypothermia, Sellors (1961) found small residual shunts in 7 patients "operated on in the early days of open heart surgery".

A large series of followed up uncomplicated atrial septal defects of the secundum type is reported by Loogen and Toker (1961) who examined 100 patients 1—6 years after operation under hypothermia. Of these patients 43 were recatheterized 4—6 weeks after operation, and 7 (16 per cent) were then found to have a residual shunt. In the remaining cases changes of the physical, electrocardiographic and roentgenological findings indicated that the defect was closed.

In a series of 30 secundum defects examined by cardiac catheterization 1—4 years after operation under hypothermia, Reindell et al. (1962) gave a full report of the roentgenological findings before and after operation. A residual left-to-right shunt was noted in 2 patients of this series.

The subjective improvement, and alterations in the physical cardiac findings and electrocardiographic and roentgenological conditions after closure of atrial septal defects are, as a rule, described together with the catheterization results, and such reports have been made by Bedford et al. (1957), Loogen and Toker (1961), and Reindell et al. (1962) among others.

An analysis of postoperative changes has been made recently by Derra, Grosse-Brockhoff and Loogen (1965). The electrocardiographic findings before and after repair of atrial septal defect have been described especially by Davies et al. (1960) and Lee and Scherlis (1962); in these series, however, no catheterization data are given to show that the defect has been closed.

Up to the present no comprehensive study of a large series of patients following open repair of atrial septal defect appears to have been reported.

Aim of the investigation. The present investigation is based on 105 patients recatheterized 17.3 months, on the average, after open correction of an *atrial septal defect of the secundum type* (ASD sec), with or without partial anomalous venous return, and 2 patients with partially anomalous venous return but with no defect.

The aim of the investigation was to compare

1. The clinical and cardiological findings before the operation and at the follow-up examination in a series of patients in whom heart catheterization

Since the long term prognosis in atrial septal defect of the secundum type, although difficult to assess, is not entirely favourable, and since the operation mortality is low Derra et al. (1965) conclude that in general operation is indicated if the left to-right shunt is 30 per cent or more of the pulmonary blood flow A predominant right to-left shunt due to raised pulmonary resistance should constitute a definite contraindication to operation, as also should therapy resistant myocardial insufficiency

The operation mortality in different series of cases is always difficult to evaluate and varies amongst other things according to the selection of cases for surgery In an analysis made by the Committee on Cardiovascular Surgery American College of Chest Physicians (1963) a mortality of 3 per cent was reported in 397 patients operated on with different closed methods, while 542 patients had undergone operation under hypothermia, with 3 per cent mortality and 1[illegible]06 patients operated on under extracorporeal circulation showed a mortality of 4 per cent.

In a series of 206 "good risk patients with uncomplicated secundum defects subjected to operation under hypothermia, Sellors (1961) reported a total mortality of 0.5 per cent, and approximately the same result was obtained by Derra et al. (1965) with only two deaths among 215 such patients. Derra states that the total operation mortality in atrial septal defect of the secundum type is now probably lower than 2 per cent in most thoracic surgical centres. In view of the gradual reduction of the operation mortality in open repair of atrial septal defects of the secundum type, it is sometimes considered that the diagnosis in itself constitutes an indication for operation (Zimmerman 1958, Mustard 1961 Gasul et al 1961) but other authors (Taussig 1960 Gross 1962 Wood 1962) are of the opinion that with small defects, which are usually compatible with a normal life, operation is not usually indicated.

Partly owing to variations in the selection of patients and the operation technique the operation results in different series of cases, often expressed as the mortality rate and the number of residual shunts, are difficult to compare. In one of the first investigations made after closed heart operations in atrial septal defect, Kirklin et al. (1956) found 6 residual shunts in 20 recatheterized patients, among 3[illegible] operated on by the Gross method. At the same time "a mild drop in pulmonary artery pressure even when it has been within the range of normal prior to operation was shown.

Sondergaard (1962) found a functionally closed defect in all except one of 66 recatheterized patients in his own operation series, although the defect was completely closed in only 54 patients. Carlgren (1961) found small residual shunts in [illegible] of a smaller series of 24 patients operated on by the same method

Residual left to-right shunts have also been demonstrated after open repair of atrial septal defects. These have usually been of a lower frequency but varying figures of up to 20 per cent are reported Bedford et al. (1957) investigated 40 patients after operation under hypothermia, including 12 with cardiac cathe

terization. A residual shunt was shown in 5 patients. Winchell and Bashour (1958) compared the haemodynamic conditions at rest before and after operation under hypothermia in 20 patients with atrial septal defect of the secundum type, and found a residual left-to-right shunt in only 1 patient, who was found at operation to have an undiscovered anomalous pulmonary vein opening into the superior vena cava. In summary these authors state that "closure of the atrial septal defect brought about the changes that one would anticipate such as reduction of pulmonary blood flow and pulmonary artery pressure to normal if it was initially elevated"

Among 65 patients with atrial septal defects of the secundum type, catheterized after operation under hypothermia, Sellors (1961) found small residual shunts in 7 patients "operated on in the early days of open heart surgery"

A large series of followed up uncomplicated atrial septal defects of the secundum type is reported by Loogen and Toker (1961) who examined 100 patients 1—6 years after operation under hypothermia. Of these patients 43 were recatheterized 4—6 weeks after operation, and 7 (16 per cent) were then found to have a residual shunt. In the remaining cases changes of the physical, electrocardiographic and roentgenological findings indicated that the defect was closed.

In a series of 30 secundum defects examined by cardiac catheterization 1—4 years after operation under hypothermia, Reindell et al. (1962) gave a full report of the roentgenological findings before and after operation. A residual left-to-right shunt was noted in 2 patients of this series.

The subjective improvement, and alterations in the physical cardiac findings and electrocardiographic and roentgenological conditions after closure of atrial septal defects are, as a rule, described together with the catheterization results, and such reports have been made by Bedford et al. (1957) Loogen and Toker (1961) and Reindell et al. (1962) among others.

An analysis of postoperative changes has been made recently by Derra, Grosse-Brockhoff and Loogen (1965). The electrocardiographic findings before and after repair of atrial septal defect have been described especially by Davies et al. (1960) and Lee and Scherlis (1962) in these series, however no catheterization data are given to show that the defect has been closed.

Up to the present no comprehensive study of a large series of patients following open repair of atrial septal defect appears to have been reported.

Aim of the investigation. The present investigation is based on 105 patients recatheterized 17.3 months, on the average, after open correction of an *atrial septal defect of the secundum type* (ASD sec) with or without partial anomalous venous return, and 2 patients with partially anomalous venous return but with no defect.

The aim of the investigation was to compare

1. The clinical and cardiological findings before the operation and at the follow-up examination in a series of patients in whom heart catheterization

had proved complete closure of the defect.

2 The haemodynamic findings at rest before and after the operation.

3 The haemodynamic conditions in a number of these patients, during work after the operation, with conditions in normal persons.

4 The haemodynamic findings at rest and during work in a number of patients, both before and after the operation in greater detail and also to compare these results with conditions in normal persons.

Case material

Collection of the material was begun in 1958, when open repair under hypothermia was introduced as a routine operation method for atrial septal defect of the secundum type at the Department of Thoracic Surgery University Hospital, Uppsala. Up until June 1964 115 patients with this diagnosis had been operated on by V O Björk personally head of the department at that time. Of these, 107 patients were followed up and form the basis of this study Five patients were not available for follow up examination, and a further three patients had died.

The majority of these patients had been remitted to the Cardiac Division of the Medical or Paediatric Medical Clinic University Hospital, Uppsala, from different hospitals, with a preliminary diagnosis such as congenital heart disease or atrial septal defect" for investigation and decision as regards surgery The diagnosis was then established by means of a complete cardiological investigation. The indication for operation was left to-right shunt on the atrial level of at least 30 % of the pulmonary blood flow In no case was there a predominant right-to-left shunt on the atrial level, or any other contraindication for operation.

Mortality There was no primary operation mortality The total mortality hitherto has comprised 3 patients (2.6 %) One 33-year old woman died of a cerebral embolus 9 days after the operation. In one 42-year old woman a postoperative regularized fibrillation necessitated the continuation of anticoagulant therapy after her discharge from hospital This patient died at her local hospital 8 months after the operation, of a cerebro-vascular complication which was probably drug induced. The third patient, a 35-year old woman, died 3 years after the operation in cardiac failure. At the operation a left to-right 80 % shunt was found, and moderate pulmonary hypertension with a systolic pulmonary arterial pressure of 50 mm Hg. Roentgenologically this patient exhibited marked cardiac enlargement with a relative volume of 1420 ml/m² body surface area, expressing pronounced myocardial insufficiency Postoperatively there was no residual shunt, and there was some subjective functional improvement, but there was a manifest, therapy-resistant cardiac insufficiency with pronounced cardiac enlargement and a roentgenological volume of 1000 ml/m² body surface area.

Age and sex. The patients were divided into the following three age groups according to age at the time of operation.

Age group A comprised a paediatric group of 50 patients who were operated on before the age of 15 years.

had proved complete closure of the defect.

2 The haemodynamic findings at rest before and after the operation.

3 The haemodynamic conditions in a number of these patients, during work, after the operation, with conditions in normal persons.

4 The haemodynamic findings at rest and during work in a number of patients, both before and after the operation, in greater detail, and also to compare these results with conditions in normal persons.

CHAPTER II

Case material

Collection of the material was begun in 1958, when open repair under hypothermia was introduced as a routine operation method for atrial septal defect of the secundum type at the Department of Thoracic Surgery University Hospital, Uppsala. Up until June 1964 115 patients with this diagnosis had been operated on by V O Björk personally head of the department at that time. Of these, 107 patients were followed up and form the basis of this study Five patients were not available for follow-up examination, and a further three patients had died.

The majority of these patients had been remitted to the Cardiac Division of the Medical or Paediatric Medical Clinic University Hospital, Uppsala, from different hospitals, with a preliminary diagnosis such as congenital heart disease or atrial septal defect" for investigation and decision as regards surgery The diagnosis was then established by means of a complete cardiological investigation. The indication for operation was a left-to-right shunt on the atrial level of at least 30 % of the pulmonary blood flow In no case was there a predominant right to-left shunt on the atrial level, or any other contraindication for operation.

Mortality There was no primary operation mortality The total mortality hitherto has comprised 3 patients (2.6 %) One 33-year old woman died of a cerebral embolus 9 days after the operation. In one 42 year old woman a postoperative regularized fibrillation necessitated the continuation of anticoagulant therapy after her discharge from hospital. This patient died at her local hospital 2 months after the operation, of a cerebro-vascular complication which was probably drug induced. The third patient, a 35-year old woman, died 3 years after the operation in cardiac failure. At the operation a left to-right 80 % shunt was found, and moderate pulmonary hypertension with a systolic pulmonary arterial pressure of 50 mm Hg Roentgenologically this patient exhibited marked cardiac enlargement with a relative volume of 1420 ml/m² body surface area, expressing pronounced myocardial insufficiency Postoperatively there was no residual shunt, and there was some subjective functional improvement, but there was a manifest, therapy-resistant cardiac insufficiency with pronounced cardiac enlargement and a roentgenological volume of 1000 ml/m² body surface area.

Age and sex The patients were divided into the following three age groups according to age at the time of operation.

Age group A comprised a paediatric group of 50 patients who were operated on before the age of 15 years.

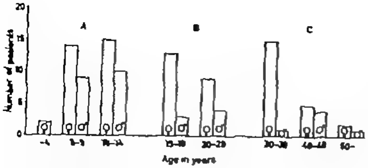

Fig 1 Distribution of patients at time of operation, by age and sex.

Age group B comprised a group of 29 young adults who were operated on at the ages of 15—29 years.

Age group C comprised a group of 28 older adults, who at the time of operation were 30 years old or older

The youngest patient was 3 years old at the time of operation, and the oldest 62 years.

The material consisted of 75 women and 32 men, the ratio of women to men being thus 2 3 1 The sex distribution varied somewhat in the different age groups. In age group A there were 31 girls and 19 boys (ratio 1 6 1) Age group B comprised 22 women and 7 men (ratio 3 1 1) and age group C 22 women and 6 men (ratio 3 7 1) The age and sex distributions at the time of operation can be seen in Fig 1

Operation methods Open repair of the atrial septal defect under hypothermia was performed in 94 of the 107 patients investigated. In 13 cases the operation was carried out with the aid of extracorporeal circulation In one 7 year old girl extracorporeal circulation was used because of uncertainty in the diagnosis ASD of primum type could not be excluded with certainty Two young adult patients in age group B, who had previously undergone surgery by the Sondergaard method, were re-operated on with the aid of extracorporeal circulation. Among the older adults of age group C, extracorporeal circulation was used in 3 patients in whom ASD of primum type could not be excluded with certainty and this method was also preferred in a further 7 patients with a large left to-right shunt. The surgical method for correction of ASD sec has been described in detail previously by V O Bjork et al. (1960) and for correction of anomalous venous return by V O Bjork et al. (1962)

Postoperative complications In 5 adult patients cerebral emboli occurred during the first few days postoperatively In 1 of these patients the outcome was fatal. The remaining 4 patients showed rapid clinical improvement, and on discharge from hospital there were no clinico-neurological abnormalities.

Fourteen patients, 12 of whom were older persons with a large left to-right shunt and cardiac enlargement, required postoperative respirator treatment for an average of 7 5 (1—26) days.

In one patient a cardiac rhythm disturbance (A V block III) occurred during the operation, and this necessitated continuous pacemaker treatment. In 10 adult patients local infection occurred in the thoracotomy wound, and in some cases this prolonged considerably the pe

riod of postoperative care. One child developed a bacterial hepatic venous thrombosis, and one adult patient bacterial pericarditis, but both recovered.

Period of postoperative care The duration of *hospitalisation* after the operation was, on the average, 21 (12—45) days for children, 36 (14—120) days for the younger adults and 40 (20—100) days for the older adults.

The *convalescence period* was also considerably shorter for the children, being 3.5 (2—12) weeks compared with 11.5 (12—36) weeks for the younger and 20.5 (12—60) weeks for the older adults.

Observatio time The observation time between operation and follow-up examination was, on the average, 17.3 months, with some variation between nd within the different age groups. On the a erage the children were investigated 8 (5—33) months and the adults 25 (15—70) months after the operation. This difference is explained by the fact that the children were called for follow up as routine w thin 1 year after the operation, whereas the adult patients were called in especially for this investigation, the patients who were operated on earliest being followed up first.

I the following, the term postopera tiv refers to the time of the follow-up examination.

Type f d fect At operation 55 patients were found to ha e a central secundum defect. Twenty two patients had large low secundum defect, and in 12 of them this was of the inferior ena ca a defect type w th no posterio-caudal margin. Twenty-seven patients had a sinus enosus defect, which in 17 cases was combined with partial anomalous venous return. A further 3 patients had anomalous venous return, in one case combined with a large central defect and in two cases with no apparent defect. The frequency of partial anomalous venous return in the entire material was 18.7 %. In 15 patients with a sinus venosus defect, and in two cases with no visible defect there was right-sided anomalous venous return to the superior vena cava, in two cases to the right atrium and in one patient to both the right atrium and the inferior vena cava.

Other cardiac malformations. In 5 patients other complicating cardiac malformations were found. Three women had mild valvular pulmonary stenosis. In 2 of these cases double repair was carried out at the operation, whereby the atrial septal defect was first closed, and valvulotomy was then performed. From a haemodynamic aspect, however the atrial septal defect predominated over the pulmonary stenosis, and these patients were therefore included.

Two patients with mitral insufficiency a woman and a man both of age group C, had both had rheumatic car diac disease. The man underwent operation with the aid of extracorporeal circulation, at which a mitral annuloplasty was performed at the same time. In the woman there appeared to be no indication for treating the mitral insuf ficiency when the atrial septal defect was repaired. Myocarditis had occurred in 2 children. One of them, a 7-year old boy had had viral myocarditis (influenza type A) and also, two years later rheumatic myocarditis. The other child, a girl, had had probable viral myocarditis

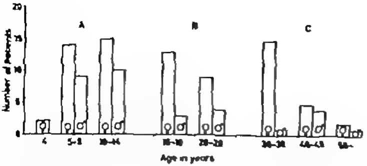

Fig 1 Distribution of patients at time of operation, by age and sex.

Age group B comprised a group of 29 young adults who were operated on at the ages of 15—29 years.

Age group C comprised a group of 28 older adults, who at the time of operation were 30 years old or older

The youngest patient was 3 years old at the time of operation, and the oldest 62 years.

The material consisted of 75 women and 32 men, the ratio of women to men being thus 2.3 : 1 The sex distribution varied somewhat in the different age groups. In age group A there were 31 girls and 19 boys (ratio 1.6 : 1) Age group B comprised 22 women and 7 men (ratio 3.1 : 1) and age group C 22 women and [illegible] men (ratio 3.7 : 1) The age and sex distributions at the time of operation can be seen in Fig 1

Operation methods Open repair of the atrial septal defect under hypothermia was performed in 94 of the 107 patients investigated. In 13 cases the operation was carried out with the aid of extracorporeal circulation In one 7 year old girl extracorporeal circulation was used because of uncertainty in the diagnosis ASD of primum type could not be excluded with certainty Two young adult patients in age group B who had previously undergone surgery by the Sondergaard method, were re-operated on with the aid of extracorporeal circulation. Among the older adults of age group C, extracorporeal circulation was used in 3 patients in whom ASD of primum type could not be excluded with certainty and this method was also preferred in a further 7 patients with a large left to-right shunt. The surgical method for correction of ASD sec has been described in detail previously by V O Björk et al. (1960) and for correction of anomalous venous return by V O Björk et al. (1962)

Postoperative complications In 5 adult patients cerebral emboli occurred during the first few days postoperatively In 1 of these patients the outcome was fatal. The remaining 4 patients showed rapid clinical improvement, and on discharge from hospital there were no clinico-neurological abnormalities.

Fourteen patients 12 of whom were older persons with a large left to-right shunt and cardiac enlargement required postoperative respirator treatment for an average of 7.5 (1—26) days.

In one patient a cardiac rhythm disturbance (A V block III) occurred during the operation and this necessitated continuous pacemaker treatment. In 10 adult patients local infection occurred in the thoracotomy wound, and in some cases this prolonged considerably the pe-

older age groups is probably not an excess mortality in the men, but could perhaps be that with symptoms of the type suffered by these patients, medical advice is more often sought by women than men (Campbell and Polani, 1962)

Distributions of defect types in operation series have been reported only seldom, but the distribution in the present material is in approximate agreement with the similarly classified series of Sellors (1961) and Arntzenius et al. (1963) The central or fossa ovalis defect constituted 60—80 % of all defects. The frequency of partial anomalous venous return was in the present series 18.7 % which is in agreement with the figures of 10—20 % reported by Derra et al. (1965)

The frequency of malformations of the mitral valve in patients with atrial septal defect varies in different series (Bedford et al. 1957 Derra et al. 1965) being partly dependent on the incidence of rheumatic fever among the population, and the age composition of the material. In Sweden the incidence of rheumatic fever has long been low (Hall 1961) which may explain the low frequency of rheumatic mitral valvular disease in this series.

in her infancy In neither of these cases were valvular changes observed on examination or operation. There were no patients with both atrial septal defect and mitral stenosis (Lutembacher's syndrome) in this series.

There were no patients with a history of endocarditis lenta in this series.

Discussion

The present material comprises a series of operation cases of atrial septal defects of the secundum type, where by chance there were no severe haemodynamic complications. It has been found that in cases where partial anomalous venous return is present in addition, this produces no change either in the clinical picture or the haemodynamic findings (Kjellberg et al. 1959) and patients with such a condition were therefore included in the ASD series.

It must be accepted that in a clinical investigation of this type there will be some degree of change in the material due to time-dependent factors such as body growth. Usually it is assumed that the haemodynamic conditions will not have returned to normal after repair of an atrial septal defect of the secundum type until about a year after the operation (Reindell et al. 1962) In most of the adult patients in the present series the postoperative observation period was considerably longer but in other cases the period was shorter Nevertheless certain results obtained at the follow up examination were used for comparisons, since the observation periods in the different age groups were considered sufficiently long

The total mortality during the period covered by the investigation was 2.6 %. When however the mortality was calculated on the basis of operative and postoperative death, i e. within 10 days after the operation (Nordlund 1966) it was only 0.9 %. The two deaths occurring 2 months and 3 years after the operation, respectively were late deaths (after 10 days) and should not be included in comparisons with other operation mortality figures. This operation mortality of 0 9 % is thus of the same order of size as has been reported by Sellors (1961) and Derra et al. (1965) among others.

In evaluations of the operation risk in uncomplicated atrial septal defect of the secundum type the most suitable age for operation has been discussed. In this series the age distribution at the time of operation was in agreement with that usually seen in ASD sec (Bedford 1961 Zellos 1964) Even if the operation risk increases with advancing age, a high age is not considered in itself to be a contraindication to operation (Ellis et al. 1960) however the optimal age for closure of an atrial septal defect of the secundum type is considered to be between 5 and 15 years (Mark 1963) In the present series this corresponds to the patients in age group A, and for these patients both the period of postoperative care and the convalescence period were considerably shorter than for the young and older adults.

The sex distribution in the whole material agreed with that usually reported in secundum defects (Derra et al. 1965 Himbert et al. 1965) The reason for the predominance of women over men in the

three heart cycles was used. With high QRS amplitudes the amplification was reduced so that one mV corresponded to 5 mm, compared with the usual 10 mm. The paper speed was 50 mm/sec. The mean QRS axis in the frontal plane was calculated in the usual way with values for axis deviation according to Goldman (1960)

For checking the rhythm postoperatively usually only standard and extremity leads could be used for the first 6—8 days because of the extent of the operation wound. At the exercise tests ECG was recorded in the recumbent position, after 8 minutes of passive standing, during exercise, in the sitting position and both immediately and 4 and 10 minutes after exercise in the recumbent position. During exercise a CH lead with the indifferent electrode on the forehead was used (Sjöstrand, 1951 Holmgren and Strandell, 1961)

Phonocardiogram (PCG) The calibrated phonocardiogram was recorded by means of the same four-channel ECG direct writing apparatus with a phonopreamplifier Usually filters with nominal frequencies of 25 c/s and 100 c/s, and an auditory amplification (Kjellberg et al. 1959) were used. The paper speed was 100 mm/sec. The recordings were made after normal expiration, over the second right, the second and third left and the fourth left intercostal spaces, and over the apex. Special respiratory phonocardiograms" for the evaluation of the second sound during ordinary inspiration and expiration were recorded. The time interval between the sound components was determined from the mean of at least 5 measurements, the interval being measured between the initial maximal amplitudes of the different components.

Basal metabolic rate The basal oxygen uptake was measured by means of double determinations of ten minutes duration each, using a Spirograf Krogh or "Spirograf IV" (Elema-Schönander Ltd., Stockholm)

Physical work capacity A work test with step-wise increases of the load (Sjöstrand, 1947 Wahlund, 1948) was carried out in the usual way on an electrically braked bicycle (Holmgren and Mattsson, 1954) The heart rate was determined after 2, 4 and 6 minutes, and the respiratory rate was counted after about 5 minutes at each load. The ECG was monitored continuously on the oscilloscope, and was recorded after 5 minutes at each load. For children under 12 years of age the first load was usually 100 kpm/min, for older children and women 200 kpm/min and for men 300 kpm/min. The test was discontinued when the pulse rate reached approximately 170 beats/min, or earlier in the event of objective or subjective signs of an abnormal reaction. The work capacity corresponding to a heart rate of 170 beats/min (PWC_{170}) was obtained by means of extrapolation or interpolation and was expressed as kpm/min per kg body weight. Work capacities of 600 kpm/min for women and 900 kpm/min for men were usually regarded as normal. The children were evaluated according to Sterky (1963)

Heart volume. The heart volume was determined with the patient in the sitting position according to the method of Jonsell (1939) and the relative heart

CHAPTER III

Methods

The mode of investigation was the same preoperatively as at the follow up examination. On both occasions the patient was hospitalized, the period of hospitalization being about 7 days for the preoperative examination and 3—4 days for the follow up

In all cases these investigations comprised a general clinical examination with full examination of the physical cardiac state electrocardiogram and phonocardiogram, chest roentgenogram and cardiac catheterization. On catheterization the pressure and flow were determined at rest and during exercise both pre and postoperatively in 18 patients, using the same work load on each occasion, and postoperatively alone in 51 patients.

General clinical examination Physical examination was performed personally by the author in all of the follow-up and also in most of the preoperative investigations, particularly in the children. The case history data concerning the symptoms and functional capacity were evaluated and used as a basis for division into function classes. For adults, function classes as suggested by the New York Heart Association (1964) were used and for children a modification of Davidsen s classification (1960) The general condition was assessed with especial regard to cardiac failure and complicating diseases, and to any further congenital malformations.

The physical cardiac state was evaluated with respect to palpatory precordial activity and auscultatory findings. The palpatory findings were assessed, and signs of increased right ventricular activity were noted. The intensity of the first sound, the degree and variability of splitting of the second sound and the amplitude of the pulmonary component were assessed. The distribution and site of the murmur were determined and the systolic murmurs graded according to Levine & Harvey (1959) at the position of their maxima. Routine blood and urinary analyses were carried out.

Electrocardiogram (ECG) In the great majority of cases the ECG was recorded with a four-channel direct writing apparatus (Mingograf 42 Elema Schönander Ltd., Stockholm) and in only a few patients before 1959 was the recording made on a three-channel apparatus (Triplex, Elema) Leads I II III aVR, aVL and aVF were used, and also in adults precordial leads V_1—V_7 and in children precordial leads V_1—V_8.

On evaluation of the QRS complex and the P and T waves, the amplitudes were measured from the isoelectrical line, i. e. a line drawn between two TP segments The mean value of at least

blood. The left-to-right shunt expressed in this way has been compared with the ratio of the pulmonary blood flow $\dot{Q}_p$ to the systemic flow $\dot{Q}_s$ (Table 2). On the basis of these considerations the following three "shunt groups" were used.

Shunt group 1. Left-to-right shunt of less than 50 % of the pulmonary blood flow corresponding to a $\dot{Q}_p : \dot{Q}_s$ ratio of less than 2 : 1.

Shunt group 2. Shunt of 50—65 % corresponding to a $\dot{Q}_p : \dot{Q}_s$ ratio equal to or more than 2 : 1 but less than 3 : 1.

Shunt group 3. Shunt of 66 % or more, corresponding to a $\dot{Q}_p : \dot{Q}_s$ ratio equal to or more than 3 : 1.

The pressure and ECG recordings were made on a direct-writing four-channel ECG apparatus (Mingograf 42). The mean pressure was obtained by electrical integration. Pressures were usually recorded continuously on withdrawal curves from the pulmonary capillary venous position to the superior vena cava for the evaluation of any valvular stenoses. In many cases the pressures in the left atrium and ventricle could be recorded preoperatively via the defect.

No complications occurred on right heart catheterization either preoperatively or at the follow-up examination, nor at the preoperative left heart catheterization performed in 47 patients.

For flow determination the catheter was placed in the pulmonary artery. The cardiac output was measured by the direct Fick method. Pressure recordings were made and blood samples taken during the 5th to 8th minutes at rest and 4th to 6th minutes during exercise. Expired air was collected for 10 minutes

Table 2. Size of left-to-right shunt expressed as per cent of pulmonary blood flow, compared with $\dot{Q}p:\dot{Q}s$ ratio.

with the patient at rest, and for 3 minutes during exercise, between the 3rd and 6th minute of each load, with the Douglas bag technique. Gas analyses were performed according to the Haldane technique (Enghoff 1946). Normal values for oxygen consumption were obtained from current tables (Harris and Benedict, 1919; Nadas, 1963).

Oxygen saturation. In most cases, where repeated oxygen saturation determinations were made at short intervals, a Kipp haemoreflectometer (Kipp and Sons Company, Delft, the Netherlands) was usually used, according to the method originally described by Zijlstra (1953). This method was employed in comparisons of pre- and postoperative saturation values. For flow determinations the oxygen saturation was measured by spectrophotometry of haemolysed whole blood, as described by Holmgren and Pernow (1959). The haemoglobin concentration was determined spectrophotometrically as cyanmethaemoglobin.

TABLE 1 Heart size ml/m^2 BSA, according to X ray groups in children, women and men.

Heart size	Children	Women	Men	
Normal	<350	<450	<500	ml/m^2 BSA
Slight enlargement	>350—500	>450—600	>500—650	»
Moderate enlargement	>500—650	>600—750	>650—800	»
Pronounced enlargement	>650	>750	>800	»

volume is given in ml/m^2 body surface area. The group classification can be seen in Table 1

Lung function tests The lung volumes and ventilation capacity were determined with a "Spirokombi" (Kifa Ltd., Stockholm) The vital capacity (VC) forced expiratory volume in one second ($FEV_{1.0}$) and maximum voluntary ventilation with a fixed respiratory frequency of 40 (MVV_{40}) and with a free respiratory frequency (MVV_f) were measured. By FEV % is meant $FEV_{1.0}$ expressed as a percentage of VC or FVC (forced vital capacity) depending on which is the greater

Cardiac catheterization. Before the first catheterization the patient was well informed about the investigation there were no difficulties in obtaining the patient's cooperation for follow up catheterization after the operation. In the morning, approximately 1 hour before the catheterization the children were given a small dose of morphine (5—7 mg) subcutaneously and the adults were given a small oral dose of Pentymal (0 1 —0 2 g) The catheterization was performed with the patient in the recumbent position. A polyethylene catheter was introduced into the brachial artery by the usual percutaneous technique. The venous catheter was usually introduced via an exposed superficial cubital vein but in some cases, especially children, the saphenous vein was preferred. In most cases the defect was demonstrated preoperatively by means of the catheter In many cases, especially with catheterization via the superior vena cava, a good idea of the position of the defect in the septum could be obtained by manipulation of the catheter as has been described by Gotzsche (1962) Shunts were usually determined preoperatively from the oxygen saturation values with relatively rapid withdrawal from the pulmonary artery to the superior vena cava. An increase in oxygen saturation of 10 per cent in one set of samples between the superior vena cava and the pulmonary artery is regarded as evidence of a left to-right shunt (Nadas, 1963) It is routine at our Centre to express the size of the left to-right shunt as per cent of the pulmonary blood flow Q % LR, (Hamilton and Dow 1962) as follows

$$Q\,\%\,LR = \frac{C_{PA_{O_2}} - C_{\bar{v}_{O_2}}}{C_{PV_{O_2}} - C_{\bar{v}_{O_2}}}$$

$C_{PV_{O_2}}$ and $C_{PA_{O_2}}$ are the oxygen contents of pulmonary vein and pulmonary artery samples, respectively and $C_{\bar{v}_{O_2}}$ is the oxygen content of mixed venous

blood. The left-to-right shunt expressed in this way has been compared with the ratio of the pulmonary blood flow $\dot{Q}_p$, to the systemic flow $\dot{Q}_s$ (Table 2). On the basis of these considerations the following three shunt groups were used:

Shunt group 1. Left-to-right shunt of less than 50 % of the pulmonary blood flow corresponding to a $\dot{Q}_p$: $\dot{Q}_s$ ratio of less than 2 : 1.

Shunt group 2. Shunt of 50—65 %, corresponding to a Q_p : $\dot{Q}_s$ ratio equal to or more than 2 : 1 but less than 3 : 1.

Shunt group 3. Shunt of 66 % or more, corresponding to a Q_p : $\dot{Q}_s$ ratio equal to or more than 3 : 1.

The pressure and ECG recordings were made on a direct writing four channel ECG apparatus (Mingograf 42). The mean pressure was obtained by electrical integration. Pressures were usually recorded continuously on withdrawal curves from the pulmonary capillary venous position to the superior vena cava for the evaluation of any valvular stenoses. In many cases the pressures in the left atrium and ventricle could be recorded preoperatively via the defect.

No complications occurred on right heart catheterization either preoperatively or at the follow-up examination, nor at the preoperative left heart catheterization performed in 47 patients.

For flow determination the catheter was placed in the pulmonary artery. The cardiac output was measured by the direct Fick method. Pressure recordings were made and blood samples taken during the 5th to 8th minutes at rest and 4th to 6th minutes during exercise. Expired air was collected for 10 minutes

with the patient at rest, and for 3 minutes during exercise, between the 3rd and 6th minute of each load, with the Douglas bag technique. Gas analyses were performed according to the Haldane technique (Enghoff 1946). Normal values for oxygen consumption were obtained from current tables (Harris and Benedict, 1919; Nadas, 1963).

Oxygen saturation. In most cases, where repeated oxygen saturation determinations were made at short intervals, a Kipp haemoreflectometer (Kipp and Sons Company, Delft, the Netherlands) was usually used, according to the method originally described by Zijlstra (1953). This method was employed in comparisons of pre- and postoperative saturation values. For flow determinations the oxygen saturation was measured by spectrophotometry of haemolysed whole blood, as described by Holmgren and Pernow (1959). The haemoglobin concentration was determined spectrophotometrically as cyanmethemoglobin.

Statistics. The arithmetical mean, standard deviation (SD) and standard error of the mean (SE) were calculated by the conventional methods. Student's t test was used to determine the significance of the differences in the various variables between preoperative and postoperative values. The studies of relations between the different variables were performed on the basis of the correlation coefficients where the significance was also determined by the t test (Snedecor 1956).

The significance levels applied were as follows

$0.05 \geq P > 0.01 = (*)$
$0.01 \geq P > 0.001 = (**)$
$0.001 \geq P = (***)$

These values correspond to the usual terms "probably significant", "significant" and "highly significant" respectively.

CHAPTER IV

Clinical findings before and after operation

Growth and physical development

The height and weight in relation to age were determined in 66 patients below 20 years of age (45 girls and 21 boys). There was some tendency to underweight, especially in the younger patients, but in only a few were the values found to be outside the normal (± 2 SD) range limits for Swedish children (Karlberg & Iggbom, 1959) as can be seen in Fig. 2. In some patients the weight was lower than the normal at the follow-up examination also, in spite of a normal weight increase.

Height in relation to age at operation. In 61 of the 66 patients the height in relation to age was within the normal range for healthy Swedish children. In 2 boys the height was below the lower range limit and in 2 other boys above the upper limit, but in all four boys the weight was normal. In one patient there were hereditary factors to explain her short stature (a Lapp girl).

Weight in relation to height at operation. Only in 5 patients, 4 girls and 1 boy was the weight found to be below the normal limit, but in all of these patients except one the height-age relationship was normal. The exception was a 14-year old boy who was unusually tall and gracile with a height of 20 cm above and a weight of 5 kg below the normal limits of variation. One girl had a pronounced weight excess.

Height in relation to age at follow-up examination. At the follow-up examination it was found that the height increase was normal, and agreed with the growth diagram. In 2 out of 3 patients whose preoperative height lay somewhat outside the normal limits of variation, the height increase was normal. The third, the gracile boy mentioned above, had increased in height by a further 13 cm to 203 cm in 18 months.

Weight in relation to height at follow-up examination. In 9 girls at the age of puberty the weight increase was rather more pronounced than the normal. In two of these the weight before the operation lay below the normal limit. In two patients the weight still lay below the normal limit in spite of a normal weight increase. One 18-year old girl who was considerably overweight preoperatively increased a further 20 kg. In the remaining patients the weight increase was normal. Preoperatively the weight in relation to height lay near the lower normal limits in patients up to 15 years of age but postoperatively there was a weight increase which meant that the deviation from the mean value diminished significantly (*).

In 41 patients of ages 20—67 years, the weight—height relationships showed no special tendencies either pre- or postoperatively.

Statistics. The arithmetical mean, standard deviation (SD) and standard error of the mean (SE) were calculated by the conventional methods. Student's t test was used to determine the significance of the differences in the various variables between preoperative and postoperative values. The studies of relations between the different variables were performed on the basis of the correlation coefficients where the significance was also determined by the t test (Snedecor 1956).

The significance levels applied were as follows

$0.05 > P > 0.01 = (*)$
$0.01 > P > 0.001 = (**)$
$0.001 > P = (***)$

These values correspond to the usual terms "probably significant" "significant" and "highly significant" respectively.

CHAPTER IV

Clinical findings before and after operation

Growth and physical development

The height and weight in relation to age were determined in 66 patients below 20 years of age (45 girls and 21 boys). There was some tendency to underweight, especially in the younger patients, but in only a few were the values found to lie outside the normal ($\pm$ 2 SD) range limits for Swedish children (Karlberg & Iggbom, 1959), as can be seen in Fig. 2. In some patients the weight was lower than the normal at the follow-up examination also, in spite of a normal weight increase.

Height in relation to age at operation. In 61 of the 66 patients the height in relation to age was within the normal range for healthy Swedish children. In 2 boys the height was below the lower range limit, and in 2 other boys above the upper limit, but in all four boys the weight was normal. In one patient there were hereditary factors to explain her short stature (a Lapp girl).

Weight in relation to height at operation. Only in 5 patients, 4 girls and 1 boy, was the weight found to be below the normal limit, but in all of these patients except one the height-age relationship was normal. The exception was a 14-year old boy who was unusually tall and gracile, with a height of 20 cm above and a weight of 5 kg below the normal limits of variation. One girl had a pronounced weight excess.

Height in relation to age at follow-up examination. At the follow up examination it was found that the height increase was normal, and agreed with the growth diagram. In 2 out of 3 patients whose preoperative height lay somewhat outside the normal limits of variation, the height increase was normal. The third, the gracile boy mentioned above, had increased in height by a further 13 cm to 205 cm in 16 months.

Weight in relation to height at follow-up examination. In 9 girls at the age of puberty the weight increase was rather more pronounced than the normal. In two of these the weight before the operation lay below the normal limit. In two patients the weight still lay below the normal limit in spite of a normal weight increase. One 18-year old girl who was considerably overweight preoperatively increased a further 20 kg. In the remaining patients the weight increase was normal. Preoperatively the weight in relation to height lay near the lower normal limits in patients up to 15 years of age, but postoperatively there was a weight increase which meant that the deviation from the mean value diminished significantly ( ).

In 41 patients of ages 20—67 years, the weight—height relationships showed no special tendencies either pre- or postoperatively.

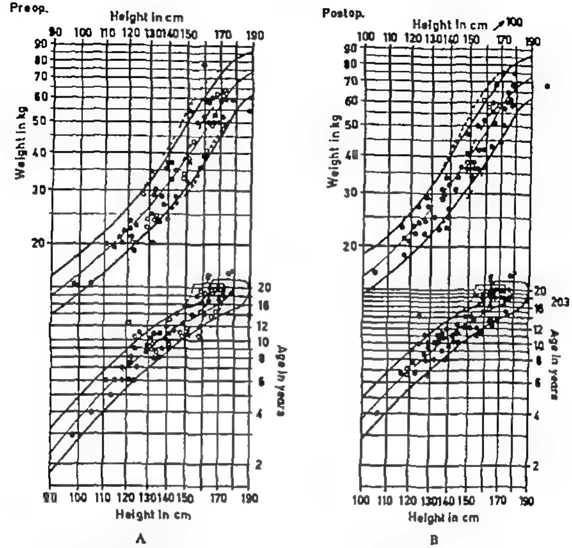

Fig 2 Physical development in 66 patients before (A) and after (B) operation. — The growth diagram gives the height in relation to age, and weight in relation to height, mean value ± SD in healthy Swedish children according to Karlberg and Igbom (1959)

Symptoms

The symptom pictures in the different age groups among a total of 44 patients with a history of functional reduction are shown in Table 3 The predominant symptoms at all ages were increased exhaustibility and breathlessness, these occurring as the only symptoms in 36 out of 38 patients in function class II two patients in age group B stated that they had no increase in exhaustibility despite their breathlessness. 9 patients also had palpitations, which in two of them were associated with precordial pain.

Only age group C included patients with pronounced subjective symptoms, 6 of them being assigned to function class III. These six patients had increased exhaustibility breathlessness and palpitations on mild effort, and 5 of them also suffered from precordial pain in association with the palpitations. One woman

of age group C had precordial pains of a suspected angina pectoris type. One patient in function class III, with pulmonary hypertension, was slightly cyanotic.

In only 14 children were recurrent infections of the upper respiratory tract observed. In the adults there appeared to be no increase in tendency to infection.

Murmurs had been detected during the first year of life in only 10 cases. In [illegible] patients the murmur was discovered

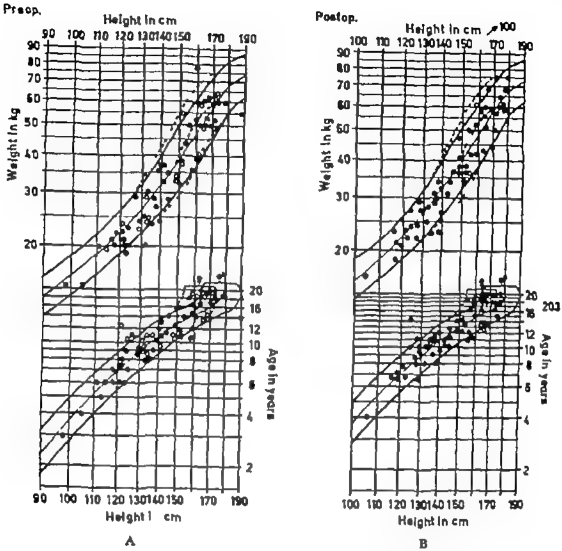

Fig 2 Physical development in 66 patients before (A) and after (B) operation. — The growth diagram gives the height in relation to age, and weight in relation to height, mean value ± SD in healthy Swedish children, according to Karlberg and Iggbom (1959)

Symptoms

The symptom pictures in the different age groups among a total of 44 patients with a history of functional reduction are shown in Table 3 The predominant symptoms at all ages were increased exhaustibility and breathlessness, these occurring as the only symptoms in 36 out of 38 patients in function class II two patients in age group B stated that they had no increase in exhaustibility despite their breathlessness. 9 patients also had palpitations, which in two of them were associated with precordial pain.

Only age group C included patients with pronounced subjective symptoms, 6 of them being assigned to function class III These six patients had increased exhaustibility breathlessness and palpitations on mild effort, and 5 of them also suffered from precordial pain in association with the palpitations. One woman

been subjectively free of symptoms preoperatively but deteriorated, 3 of them due to postoperative cardiac rhythm disturbances and one woman due to an abnormal increase in weight.

Exercise tests. Exercise tests were performed mainly so as to allow comparison between the physical work capacity before and after operation, but also to obtain an idea of the relationship between subjective symptoms, and objective signs of functional reduction. Exercise tests were performed by 81 patients preoperatively and by 69 at the follow-up examination.

In 68 patients comparison was made between the preoperative and postoperative values of PWC_{170}, expressed in kpm/min per kg body weight (Fig. 4) but no significant difference was noted either in the children or adults.

Preoperatively 11 patients in function class II were assessed as having a normal physical work capacity and in 9 patients in function class I this was assessed as reduced. Since breathlessness was a common symptom, it was expected that patients with a reduced physical work capacity would have a higher than normal respiratory rate in relation to the work load. This was in fact shown in only 6 patients, for whom the exercise tests were discontinued at relatively low work loads because of a high respiratory rate. In these patients lung function tests gave values within the normal limits.

In 15 patients in function class II with reduced physical work capacity there were signs of limitation of peripheral blood flow after a short period of low work load, when the pulse and respiration values were relatively high,

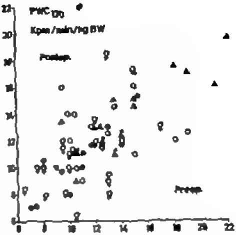

Fig. 4. Physical work capacity expressed in kpm/min per kg body weight, before and after operation.

Circles represent women, triangles men; open symbols = children, filled symbols = patients in age group B. Circles with crosses, and triangles with arrows represent patients in age group C.

the patient was forced to discontinue the exercise test because of tiredness, especially of the legs. Muscular weakness, due for example, to lack of training, may have been contributory.

Postoperatively 16 patients in function class I were assessed as having a reduced physical work capacity.

In 22 patients who had been subjectively symptom-free preoperatively there was a marked subjective improvement in the work capacity but no objective functional change at the follow-up examination.

Other investigations

Blood. In all patients except three the preoperative values for red blood cells, haemoglobin, haematocrit and sedimentation rate lay within the normal limits,

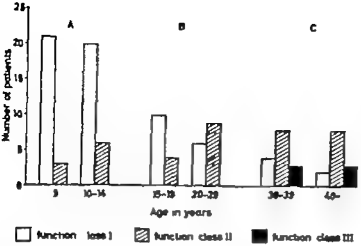

Fig 3. No. of patients in different function classes according to age groups at time of operation.

during the pre school years. In 43 patients the murmur was discovered during the school period, at an age of between 7 and 14 years. In 10 out of 28 patients in age group C the murmur was detected after the age of 30 years.

In consideration of the age distribution of the material, it was also of interest to know how the heart disease had been discovered. As shown in Table 4 the discovery was usually made during a routine examination at a Child Welfare Clinic or at school or at mass radiography an examination during pregnancy or other routine health investigations. In 78 patients the heart disease was discovered at examinations of this type. In 24 patients a murmur had been heard during the investigation of another condition. Only 5 patients had sought medical advice for symptoms which could be related to heart disease.

Functional capacity and exercise tests

Function classes The functional capacity of the patient was evaluated on the basis of the case-history data.

The *preoperative* function classes in relation to the age groups are given in Fig 3 In age group A, 41 out of 50 children were completely free of symptoms (function class I) 9 patients were assigned to function class II because of increased exhaustibility and breathlessness on moderate effort. In age group B, consisting of 29 patients of ages 15—29 years, 16 of these patients were in function class I and 13 in function class II. Out of 28 patients in age group C, only 6 were free of symptoms (function class I) 16 patients were in function class II and 6 in function class III

The functional reduction began at the age of about 20 years 51 out of 64 patients below 20 years of age were in function class I compared with only 12 out of 43 patients over this age.

At the *follow-up examination* a marked improvement of the subjective functional capacity was noted. Only 8 patients now qualified for function class II one in age group A, 3 in age group B and 4 in age group C. One of these patients in function class II showed no change and 3 patients in preoperative function class III showed improvement. 4 patients had

been subjectively free of symptoms preoperatively but deteriorated, 3 of them due to postoperati e cardiac rhythm disturbances and one woman due to an abnormal increase in weight.

Exercise tests. Exercise tests were performed mainly so as to allow comparison between the physical work capacity before and after operation, but also to obtain an idea of the relationship between subjective symptoms, and objective signs of functional reduction. Exercise tests were performed by 81 patients preoperatively and by 89 at the follow-up examination.

In 68 patients comparison was made between the preoperative and postoperative values of PWC_{170}, expressed in kpm/min per kg body weight (Fig 4) but no significant difference was noted either in the children or adults.

Preoperatively 11 patients in function class II were assessed as having a normal physical work capacity and in 9 patients in function class I this was assessed as reduced. Since breathlessness was a common symptom, it was expected that patients with a reduced physical work capacity would have a higher than normal respiratory rate in relation to the work load. This was in fact shown in only 8 patients, for whom the exercise tests were discontinued at relatively low work loads because of a high respiratory rate. In these patients lung function tests gave values within the normal limits.

In 15 patients in function class II with reduced physical work capacity there were signs of limitation of peripheral blood flow after a short period at a low work load, when the pulse and respiration values were relatively high, the patient was forced to discontinue the exercise test because of tiredness, especially of the legs. Muscular weakness, due, for example, to lack of training, may have been contributory

Postoperatively 18 patients in function class I were assessed as having a reduced physical work capacity

In 22 patients who had been subjectively symptom-free preoperatively there was a marked subjective improvement in the work capacity but no objective functional change at the follow-up examination.

Other investigations

Blood. In all patients except three the preoperative values for red blood cells, haemoglobin, haematocrit and sedimentation rate lay within the normal limits,

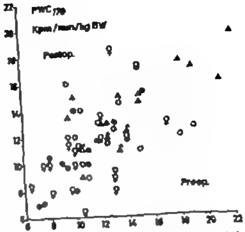

Fig. 4. Physical work capacity expressed in kpm/min per kg body weight, before and after operation.

Circles represent women, triangles men; open symbols = children, filled symbols = patients in age group B. Circles with crosses, and triangles with arrows represent patients in age group C.

according to the norm used at our laboratory (de Verdier and Killander 1965) these exceptions were two children and one adult with somewhat low blood values indicating mild anaemia. At the follow up examination the routine blood values were normal in all patients.

Urine analysis. Tests for protein and glucose and sediment determination, were performed as routine, and the results were normal in all patients both preoperatively and at the follow-up examination.

The non protein nitrogen was determined before and after the operation and was normal in all patients.

The *basal metabolic rate* was determined in all adult patients, with normal results. In no case was there any clinical sign of dysfunction of the thyroid gland, either before or after the operation.

Lung function tests The normal values were calculated according to the norm used at this laboratory The following variations from the mean values were considered normal for MVV_f and VC $\pm$ 20 % for FEV % $\pm$ 8 % (see Hallén 1964 for further references) 36 patients were examined preoperatively including 6 children, and these results lay within the normal limits.

At the follow-up examination lung function tests were carried out in a further 10 patients, with normal results.

Electroencephalogram (EEG) EEG recordings were made preoperatively in 92 patients, and in 83 of them the results were evaluated as normal In 3 children and 1 adult, the EEG was of a paroxysmal type. In 5 patients (3 children and 2 adults) other non-specific pathological changes were noted.

At the follow-up examination EEG recordings were made in 97 patients. The pathological changes recorded before the operation were still present. In 5 patients who had shown a normal EEG preoperatively non-specific pathological changes were now seen, which in two cases appeared to be related to suspected postoperative cerebral air emboli in the other three patients no definite explanation for the EEG change was found.

Discussion

The results of the preoperative height and weight determinations are in agreement with those of previous similar Scandinavian investigations of Kjellberg et al. (1959) and Davidsen (1960) Taussig (1947) pointed out that children with an atrial septal defect are often gracile, thin and underdeveloped, but according to Kjellberg et al. this feature is to be seen also in children with a large left to-right shunt via a ventricular septal defect or a patent ductus arteriosus. Although only a few patients showed weight values outside the normal range limits ($\pm$ SD) there was some tendency in the children towards low weights preoperatively At the follow up examination they showed a more normal distribution around the mean value In some patients, however the weight was lower than normal before operation as well as at the follow up examination, in spite of a normal weight increase, and this would seem to indicate that in addition to haemodynamic factors other for example constitutional factors may also

provide a reason for the slender body build which may sometimes be found in patients with an atrial septal defect.

It is to be expected that a congenital disease such as atrial septal defect of the secundum type, with its often rather mild physical manifestations, will be discovered relatively late in life. In many cases in the present series a murmur was heard on some occasion during school years, but was not regarded as a sign of organic heart disease, but was often "rediscovered" at a later examination or in connection with the onset of symptoms. The onset of the symptoms and the symptoms themselves differed somewhat in the present series from the descriptions usually given by other authors, including Bedford et al. (1957) and Davidsen (1960), but this may be explained by the fact that, with a few exceptions, this happened to be a series of haemodynamically uncomplicated secundum defects with mild symptoms and a late onset. Mild symptoms occurred in 44 out of 107 patients, and in only 6 cases were the symptoms so pronounced as to indicate function class III. together with the finding that the symptoms were seldom manifest before the age of 20 years, the present results are probably representative of the haemodynamically uncomplicated secundum defect.

When grading the functional capacity into function classes according to the degree of severity of the symptoms as reported in the case history consideration must be taken of the possible presence of non-cardiac symptoms and also of cardiac symptoms which are not necessarily due primarily to the atrial septal defect but which arise rather from some secondary deterioration of the basic general condition. For example, if the patient has been aware of his murmur since childhood, and has often been advised to avoid undue effort (e.g. has been excused from gymnastics, etc.) this may result in a reduction of his general physical fitness and thus a lowering of his physical work capacity. This may be less pronounced in patients in whom an atrial septal defect is diagnosed during a routine examination at a more advanced age. At the same time it must be taken into account that patients with a congenital heart disease such as ASD sec may become so adapted to their condition that they consider themselves free from symptoms. With a functional improvement after the operation the patient may then realise the falsity of his previous assumption. Further, a subjective improvement after the operation, which is not accompanied by any objective change, may be a nonspecific expression of the reaction of the patient to successful surgery. No objective evaluation of the functional capacity after surgical repair of atrial septal defects appears to have been reported previously. In the present series there was a number of patients before as well as after the operation with a reduced physical work capacity, but preoperatively most of the patients had symptoms, while postoperatively the majority were subjectively symptom-free, and this shows the value of objective function tests in assessing the physical work capacity of the patient. After operation on an uncomplicated ASD sec, an improvement of the physical work capacity might be expected. This capacity is governed

mainly by the capacity of the circulatory system to transport oxygen (Sjöstrand 1956) In patients with a low physical work capacity preoperatively due to reduced peripheral blood flow probably resulting from lack of physical training, closure of the defect in uncomplicated cases should not *a priori* be followed by any change in the systemic circulation and therefore in the physical work capacity Thus was analysed in the present series, and no significant change in the physical work capacity was noted after the operation. Jonsson et al. (1957) have demonstrated further that there is no relationship between magnitude of shunt and physical work capacity

The ventilation capacity in those patients in whom this was tested lay within the normal limits, with no difference between the pre- and postoperative values. These patients also showed preoperatively only a slight raise in the systolic pressure in the pulmonary artery and a low pulmonary resistance at rest. On the other hand in atrial septal defect with a high systolic pressure in the pulmonary artery regardless of whether this was caused by a greatly increased pulmonary blood flow or a raised pulmonary resistance, Woolf (1963) found signs of low compliance and high non-elastic resistance as an explanation for the "excessive hyperventilation" on exercise, while Gazetopoulos and Davies (1966) found no relationship between different haemodynamic parameters and excessive ventilatory rate during exercise in patients with left to-right shunts, but discuss the possibility of a relationship betwen tissue hypoxia and ventilatory response.

In order to evaluate any cerebral anoxic damage associated with the operation, electroencephalographic recordings were made before the operation and at the follow up examination. None of the patients showed clinico-neurological signs of cerebral dysfunction at the follow-up examination. In three patients, for whom both the operation and the post operative period were free of complications, newly manifest nonspecific pathological changes were seen, for which no definite explanation was found.

Summary

The growth and physical development in 66 patients below the age of 20 years is reported. In only a few patients did the preoperative values lay outside the ± 2 SD limits of variation for Swedish children, which is in agreement with previous findings. In the children, however there was some tendency to low weights preoperatively but at the follow up examination a weight increase was noted, the deviation from the mean value diminishing significantly this can be interpreted as a nonspecific sign of improvement in this age group.

The murmur was usually discovered at a routine examination during the preschool or school period. Only 5 of the 107 patients had sought medical advice for symptoms which could be related to the cardiac disorder

Preoperatively 44 patients had symptoms, 38 in function class II and 6 in function class III The functional deterioration occurred after the age of 20 years. Reduction in physical work capacity probably due to lack of physical

training, was noted as an average result preoperatively and was unchanged postoperatively. Postoperatively there was, however subjective improvement in the work capacity which may have been an expression of the general nonspecific reaction after the operation.

There was no postoperative change in the physical work capacity as expressed in PWC_{170}, compared with the preoperative values.

Lung function tests in 36 patients gave normal results both pre- and postoperatively.

No signs of cerebral anoxic damage were found by EEG or clinico-neurological routine examination after the operation.

mainly by the capacity of the circulatory system to transport oxygen (Sjostrand 1956) In patients with a low physical work capacity preoperatively due to reduced peripheral blood flow probably resulting from lack of physical training closure of the defect in uncomplicated cases should not *a priori* be followed by any change in the systemic circulation and therefore in the physical work capacity This was analysed in the present series, and no significant change in the physical work capacity was noted after the operation. Jonsson et al. (1957) have demonstrated further that there is no relationship between magnitude of shunt and physical work capacity

The ventilation capacity in those patients in whom this was tested lay within the normal limits, with no difference between the pre and postoperative values. These patients also showed preoperatively only a slight raise in the systolic pressure in the pulmonary artery and a low pulmonary resistance at rest. On the other hand in atrial septal defect with a high systolic pressure in the pulmonary artery regardless of whether this was caused by a greatly increased pulmonary blood flow or a raised pulmonary resistance, Woolf (1963) found signs of low compliance and high non elastic resistance as an explanation for the "excessive hyperventilation on exercise, while Gazetopoulos and Davies (1966) found no relationship between different haemodynamic parameters and excessive ventilatory rate during exercise in patients with left to-right shunts, but discuss the possibility of a relationship betwen tissue hypoxia and ventilatory response.

In order to evaluate any cerebral anoxic damage associated with the operation electroencephalographic recordings were made before the operation and at the follow-up examination. None of the patients showed clinico-neurological signs of cerebral dysfunction at the follow-up examination. In three patients, for whom both the operation and the post operative period were free of complications, newly manifest nonspecific pathological changes were seen, for which no definite explanation was found.

In the children, however there was some tendency to low weights preoperatively but at the follow-up examination a weight increase was noted the deviation from the mean value diminishing significantly this can be interpreted as a nonspecific sign of improvement in this age group.

The murmur was usually discovered at a routine examination during the preschool or school period. Only 5 of the 107 patients had sought medical advice for symptoms which could be related to the cardiac disorder

Preoperatively 44 patients had symptoms, 38 in function class II and 6 in function class III The functional deterioration occurred after the age of 20 years. Reduction in physical work capacity probably due to lack of physical

After operation. In the immediate postoperative period auscultation showed the second sound to be *still constantly* split in 72 patients, and the pulmonary component was accentuated in 90 patients.

On PCG recording, however the splitting was *found to* show some physiological variation in 45 patients. The interval between the sound components had decreased somewhat, compared with the preoperative findings, being 4.6 (2—7) csec, on the average with no difference between the age groups. The pulmonary component was accentuated in 36 patients.

At follow-up examination. On auscultation the second sound at the follow-up examination was variable in 64 patients and the pulmonary component was accentuated in [illegible] patients.

PCG recording, however showed a definitely inconstant splitting of the second sound in 97 patients, where the time interval between the sound components varied by 1—2 csec. The time interval between the aortic and pulmonary components was now on the average, 5.0 (3—8) csec. *In* 34 patients, including 18 children, the pulmonary component was accentuated.

Thus before the operation constant splitting of the second sound was registered in 96 of the 107 patients, while at the follow-up examination the splitting of the sound varied *during the respiratory* cycle by 1—2 csec in a similar number of cases. The relationship between the amplitudes of the sound components also varied. Of the 34 patients in whom a residual predominant pulmonary component was found at follow-up

TABLE 5. Second heart sound on PCG registration before and after operation and at follow-up examination. Time interval in csec between aortic (A_2) and pulmonary (P_2) components of the second heart sound on expiratory phase.

Follow-up	10	97	34	5.0 (3—8)

examination, 18 were children. PCG recording was superior to auscultation as regarded the evaluation of the amplitude of the sound components and the variations in time interval between the aortic and pulmonary components of the second sound.

Third heart sound. In 19 cases, including 13 children, a diastolic extra sound was heard.

This sound was always recorded together with a diastolic filling murmur in patients with a large left-to-right shunt, and was *interpreted as a diastolic* filling sound. This appeared to be absent after the operation.

Systolic murmurs. Table 6 shows the incidence of systolic murmurs heard on auscultation at the three examinations.

Before operation. In 73 patients the systolic murmur was *of intensity* grade III, with an equal distribution between

CHAPTER V

Physical cardiac findings and chest roentgenogram before and after operation

Precordial palpation

Preoperatively there were palpatory signs of increased activity of the right ventricle in 76 patients. At the *postoperative* examination some normalization of these findings was observed the right ventricular activity being considered increased in only 27 patients, 18 of whom were children. Obviously no close correlation between palpatory findings and haemodynamic conditions can be made, but the present results may indicate some relationship between the change in palpatory findings and the decreased load on the right ventricle.

Auscultation and phonocardiogram

The first heart sound was evaluated over the 4th left intercostal space, parasternally and the second sound and systolic murmur over the pulmonary area (2nd and 3rd left intercostal spaces parasternally) The diastolic extra sounds and murmurs were evaluated over the tricuspid area (4th left intercostal space, parasternally or midsternally) The second sound and systolic murmur were also evaluated during the more immediate postoperative period at about 2 weeks after the operation Separate evaluation of the aortic and pulmonary components of the second sound may be difficult The criterion used for an accentuated pulmonary component was that its distribution over the precordium should be increased to regions outside the customary pulmonary area, especially if in such regions the pulmonary component was of greater amplitude than the aortic component.

First heart sound Preoperatively the first heart sound was considered to be louder than normal in 43 patients, with an approximately equal distribution between children and adults.

At the *follow-up* examination this heart sound was considered normal in all except 12 cases.

Second heart sound. Table 5 shows the results of evaluation of the second sound in the entire series before and also immediately after the operation and at the follow up examination.

Before operation On auscultation constant splitting of the second sound was found in all cases, and accentuation of pulmonary component in all except 5

On PCG recording the time interval between the aortic and pulmonary components of the second sound was found to be constant in all patients except 11 and was, on the average 5.5 (3—8) *centiseconds (csec) No difference* was seen between the different age groups. In the 11 patients in whom the second sound varied with respiration, the interval variation between the sound components was less than 1 csec. The pulmonary component was accentuated in 60 patients.

After operation. In the immediate postoperative period auscultation showed the second sound to be still constantly split in 72 patients, and the pulmonary component was accentuated in 90 patients.

On PCG recording, however the splitting was found to show some physiological variation in 45 patients. The interval between the sound components had decreased somewhat, compared with the preoperative findings, being 4.6 (2—7) csec, on the average with no difference between the age groups. The pulmonary component was accentuated in 36 patients.

At follow-up examination. On auscultation the second sound at the follow-up examination was variable in 64 patients and the pulmonary component was accentuated in 93 patients.

examination, 18 were children. PCG recording was superior to auscultation as regarded the evaluation of the amplitude of the sound components and the variations in time interval between the aortic and pulmonary components of the second sound.

Third heart sound. In 19 cases, including 13 children, a diastolic extra sound was heard.

This sound was always recorded together with a diastolic filling murmur in patients with a large left-to-right shunt, and was interpreted as a diastolic filling sound. This appeared to be absent after the operation.

Systolic murmurs. Table 6 shows the incidence of systolic murmurs heard on auscultation at the three examinations.

Before operation. In 73 patients the systolic murmur was of intensity grade III with an equal distribution between

TABLE 6. Incidence of patients with systolic murmurs of different grades heard on auscultation before and after operation and at follow-up examination.

	Systolic heart murmur grade IV	III	II	I	0
Preop.	13	73	19	2	—
Postop.	—	3	40	41	23
Follow up	—	2	38	57	10

children and adults. A systolic murmur of grade II was found in 19 patients, and of grade IV in 13 patients. In two adult patients a systolic murmur of grade I was heard.

After operation. After the operation the systolic murmur was attenuated and in only 3 patients was it of intensity grade III Systolic murmurs of grade II were heard in 40 patients, the majority being children. A low pitched grade I systolic murmur was heard in 41 patients, while in 23 patients no murmur at all was heard

At follow-up examination At the follow up examination a systolic murmur of grade III was heard in 2 patients. A systolic murmur of grade II was heard in 38 patients, this figure thus being essentially unchanged compared with the immediately postoperative findings. On the other hand a systolic murmur of grade I was now somewhat more frequent, being heard in 57 patients.

The PCG recording was in essential agreement with the auscultatory findings except in three patients, in whom murmurs of grade I were heard on auscultation but were not confirmed by PCG Before and after operation the murmur was of the early systolic ejection type, but postoperatively both the amplitude and intensity were lower and the duration usually somewhat shorter

Diastolic murmur preoperative The typical early mid-diastolic filling murmur was only heard before the operation, and then in 60 patients.

The PCG recording was in agreement preoperatively with the auscultatory findings regarding the distribution and intensity of the systolic murmur but on the other hand in 5 cases a diastolic murmur definitely heard on auscultation was not registered by PCG

Systemic blood pressure

The arterial blood pressure was measured by the usual cuff method, with an aneroid manometer checked against a mercury column.

The mean preoperative value for children was 110/70 (range 95/60—130/85) and this value remained essentially unchanged after the operation. Two adult patients had arterial hypertension with systolic pressures of 185 and 200 mm Hg and diastolic pressures of 100 mm Hg The mean preoperative value for adults was 135/80 (range 105/60—200/100) and this value remained essentially unchanged at the follow up examination (140/85 range 110/65—200/100)

Chest roentgenogram

Since it is often difficult to evaluate the *heart configuration* in patients with atrial septal defects, no detailed analysis or gradation of the different findings was made

Preoperatively it was noted, however that 82 patients had distinct dilatation

TABLE 7 Distribution of patients according to heart size as determined by chest X-ray before and after operation.

of the pulmonary artery and its central and peripheral branches. In 76 of these patients signs of enlargement of the right ventricle were seen, which in 36 cases were evaluated as pronounced. In 18 patients only moderate dilatation of the pulmonary artery was seen, and in 7 patients the configuration was considered to be normal.

At the *follow-up examination* a regression of the preoperatively increased dilatation of the central and peripheral branches of the pulmonary artery was seen. Residual dilatation of the main trunk of the pulmonary artery was observed in 81 patients; this dilatation was considered to be less pronounced than before the operation but more pronounced than the normal. In 28 patients the configuration was normal. Neither the age of the patient nor the length of time after operation appeared to influence the degree of residual dilatation of the main trunk of the pulmonary artery.

Heart volume. The results of the evaluation of the relative heart volume before the operation and at the follow-up examination are given in Table 7.

Preoperatively the heart volume was normal in 21 patients. In 58 patients there was slight enlargement of the heart, in 21 patients moderate enlargement and in only 7 patients pronounced enlargement. Preoperatively the heart volume was, on the average, 448 (315—

800) ml/m² BSA in children, 491 (325—800) ml/m² BSA in young adults and 625 (400—1260) ml/m² BSA in older adults.

At the *follow up examination* the corresponding values were 350 (240—510) 419 (260—760) and 554 (430—1260) ml/m² BSA. In the patients of all age groups the roentgenological heart volume was significantly (***) smaller postoperatively than preoperatively

Sixty patients now showed a normal heart volume and 38 a slight residual cardiac enlargement. Only 9 patients had more advanced cardiac enlargement (6 moderate and 3 pronounced) In 1 child and 3 women with residual, moderate enlargement this could be explained by postoperative cardiac rhythm disturbances viz. an AV block II in three cases, and an AV block III in one case. In the other 2 cases no explanation was found for the absence of volume reduction 2 1/2 years, on the average after the operation.

Three patients had residual pronounced cardiac enlargement at the follow-up examination. In these three patients the enlargement was probably an expression of irreversible dilatation due to myocardial damage, which had been caused preoperatively by pulmonary hypertension in one case and by myocarditis with mitral insufficiency in an other case. The third patient had atrial fibrillation both pre- and postoperatively

Discussion

The preoperative physical cardiac findings in this series of patients were in agreement with those usually described previously in uncomplicated atrial septal defect of the secundum type. The post operative findings were as expected after a satisfactory operation. Postoperative findings have been described by Loogen & Toker (1961) among others, but the value of their findings in 100 surgically repaired secundum defects is limited somewhat by the fact that only 43 of the patients underwent recatheterization, 7 of whom had a residual shunt. The present material consisted of a haemodynamically uncomplicated uniform series of surgically corrected ASD sec, in which, at follow up examination with heart catheterization it was shown that the defect was completely closed.

After repair of an atrial septal defect, the excess volume load on the right heart and pulmonary circulation disappears instantly while on the other hand structural restitution occurs gradually As a result a flow murmur can be heard over the pulmonary region, caused by turbulent flow through a still somewhat dilated pulmonary artery This means also that the second sound, partly for the same reason — reduced elasticity in the wall of the pulmonary artery (Jonsson, 1958) — is still extensively split but with some physiological variation which can be explained by a decrease in the flow volume.

In this series of patients the total number of residual murmurs was essentially greater than that reported by Loogen & Toker (1961) and Reindell et al. (1962) while, on the other hand, the frequency of murmurs of grade II was essentially the same. However a larger number of weak murmurs (grade I) were heard on auscultation.

Preoperatively 21 patients showed a normal heart olume roentgenologically while only 7 were considered to have a normal heart configuration. Dilatation of the pulmonary artery and increased vascularity of the lungs do not occur only in atrial septal defect, but these conditions without dilatation of the left atrium appear to constitute the most definite roentgenological finding

Roentgenologically compared with the preoperative findings reduced vascularity of the lungs was the first change observed after the operation, while on the other hand the main trunk of the pulmonary artery and right entricle may return to normal gradually during the year immediately following surgery Loogen & Toker (1961) found a residual cardiac enlargement in 34 % usually in older patients. In the present series a slight residual cardiac enlargement was seen roentgenologically in 38 patients (35 %) of whom 26 were children. The large proportion of children can probably be explained by the fact that they ere examined, on the average, sooner after the operation than the adults. At the routine examination 1 1/2 years, on the erage after recatheterization, only 2 children showed a residual slight cardiac enlargement, which in one of them could ha e been due partly to preoperati rheumatic carditis. In most cases, however the pulmonary artery was somewhat dilated compared with normal conditions. The relationship between age heart olume, left-to-right shunt and right entricular pressure will be discussed in chapter VII.

Slight residual cardiac enlargement did not gi rise, however to any abnormal haemodynamic changes. In isolated cases with more pronounced enlargement after the operation, this was due either to newly acquired postoperative, or irreversible preoperative factors.

Summary

The physical findings before and after operation in this series were in agreement with previous findings in uncomplicated ASD sec.

The second heart sound was preoperatively constantly split and postoperatively t was inconstantly split in 90 % of the patients, but the average time interval between the sound components was practically unchanged, viz. 5—6 csec

Systolic murmurs were heard postoperati ely in all except 10 patients, but were of a lower grade than preoperatively and can be explained by turbulent flow in the dilated pulmonary artery

All patients except 2 adults had a normal arterial blood pressure before the operation, and this remained unchanged postoperatively

The heart configuration was pathological preoperatively in all except 7 patients, with dilatation of the pulmonary artery and its central and peripheral branches. Signs of hypertrophy of the right ventricle were seen in 76 cases. Postoperatively the vascularity of the lungs was reduced compared with preoperatively while the dilatation of the main trunk of the pulmonary artery persisted for a long period and was seen in 81 of the 107 patients at the follow-up examination, though to a less pronounced extent than preoperatively

3—673006 Pettersson

800) ml/m² BSA in children, 491 (325—800) ml/m² BSA in young adults and 625 (400—1260) ml/m² BSA in older adults.

At the *follow up examination* the corresponding values were 350 (240—510) 419 (260—760) and 554 (430—1260) ml/m² BSA. In the patients of all age groups the roentgenological heart volume was significantly (***) smaller postoperatively than preoperatively

Sixty patients now showed a normal heart volume and 38 a slight residual cardiac enlargement. Only 9 patients had more advanced cardiac enlargement (6 moderate and 3 pronounced) In 1 child and 3 women with residual moderate enlargement this could be explained by postoperative cardiac rhythm disturbances, viz. an AV block II in three cases, and an AV block III in one case. In the other 2 cases no explanation was found for the absence of volume reduction 2 1/2 years, on the average, after the operation.

Three patients had residual pronounced cardiac enlargement at the follow up examination. In these three patients the enlargement was probably an expression of irreversible dilatation due to myocardial damage, which had been caused preoperatively by pulmonary hypertension in one case and by myocarditis with mitral insufficiency in another case The third patient had atrial fibrillation both pre- and postoperatively

Discussion

The preoperative physical cardiac findings in this series of patients were in agreement with those usually described previously in uncomplicated atrial septal defect of the secundum type. The postoperative findings were as expected after a satisfactory operation. Postoperative findings have been described by Loogen & Toker (1961) among others, but the value of their findings in 100 surgically repaired secundum defects is limited somewhat by the fact that only 43 of the patients underwent recatheterization, 7 of whom had a residual shunt. The present material consisted of a haemodynamically uncomplicated uniform series of surgically corrected ASD sec, in which, at follow up examination with heart catheterization, it was shown that the defect was completely closed.

After repair of an atrial septal defect, the excess volume load on the right heart and pulmonary circulation disappears instantly while on the other hand structural restitution occurs gradually As a result a flow murmur can be heard over the pulmonary region, caused by turbulent flow through a still somewhat dilated pulmonary artery This means also that the second sound, partly for the same reason — reduced elasticity in the wall of the pulmonary artery (Jonsson, 1958) — is still extensively split but with some physiological variation, which can be explained by a decrease in the flow volume

In this series of patients the total number of residual murmurs was essentially greater than that reported by Loogen & Toker (1961) and Reindell et al. (1962) while, on the other hand, the frequency of murmurs of grade II was essentially the same However a larger number of weak murmurs (grade I) were heard on auscultation.

Electrocardiographic findings before and after operation

ECG studies were made in all 107 patients both preoperatively and at the follow-up examination, with regard to rate and rhythm, the nature and duration of the P wave and the QRS complex, the direction of the mean QRS axis in the frontal plane, and T wave abnormalities. In addition, the ECG was studied with respect to arrhythmia and S-T and T changes during the immediate postoperative period.

Heart rate and rhythm

Preoperatively the heart rate was, on the average, 93 (70—150) beats per minute in the children and 78 (55—115) in the adults. In 20 children and 3 adults the heart rate was more than 100 beats per minute.

At the *follow-up* examination the corresponding figures were 81 (45—130) and 71 (40—120) respectively. Five children and 2 adults now had a heart rate of more than 100 beats per minute.

Preoperatively all patients showed *sinus rhythm* with the exception of one 62-year old woman with atrial fibrillation with a normal ventricular rate.

At the *follow-up* examination 5 patients showed residual postoperative arrhythmia. Three patients had an A V block II in two of these patients this persisted at a later examination, but in the third patient, a 12 year old girl, sinus rhythm was recorded 4 years after the operation. One patient had a postoperative A V block III which required pacemaker therapy and another patient showed therapy-resistant atrial fibrillation which had been present preoperatively.

Cardiac rhythm disturbance during the immediate postoperative period. During the entire postoperative period up to the follow-up examination, 50 patients showed sinus rhythm, the incidence being somewhat higher in young than in older patients.

In 30 patients, relatively regular supra ventricular rhythm was noted initially and on an average of 2.3 days after the operation this changed to regular sinus rhythm.

In 6 patients, sinus rhythm was recorded during the first 24 hours postoperatively and after an average of 4.1 days this changed to supraventricular rhythm, but 3.5 days later sinus rhythm was again noted in these patients.

Thus 86 of the 107 patients had regular sinus rhythm 8 days after the operation, while 21 patients showed residual postoperative arrythmia. Of these, 12 patients (5 children, and 7 adults) had regular supraventricular rhythm, which changed to sinus rhythm after an average of 29 days. 5 patients (2 children and 3 adults) showed an A V block

Preoperatively 21 patients had a normal heart volume 58 patients showed slight cardiac enlargement 21 moderate enlargement and 7 pronounced enlargement. At the follow up examination 60 patients had a normal heart volume, 38 patients showed slight cardiac enlargement and in 9 patients the enlargement was more pronounced. There was a significant (***) postoperative reduction of the heart volume in the different age groups. The children in particular showed a residual slight enlargement which may be explained by the fact that in this group the observation period was shorter than in the adults at a further follow up examination 18 months, on the average, after recatheterization, the heart volume was normal in all children except three. No abnormal haemodynamic changes were noted in association with residual slight enlargement. In the isolated cases with more pronounced cardiac enlargement postoperatively this was due either to newly acquired postoperative, or irreversible preoperative conditions.

QRS complex

In spite of large variations in the QRS complex in lead V_1, it was possible in principle to classify the different types into the four QRS patterns shown in

Fig. 5. Configuration of QRS complex in lead V_1

II In 3 of these patients sinus rhythm was recorded 3 weeks, 4 months and 4 years, respectively after the operation, but in the other 2 patients this block is still present. One 42 year old woman had a postoperative A V block III which necessitated pacemaker therapy Two patients had atrial fibrillation, which after medication altered to sinus rhythm 8 weeks and 12 weeks, respectively after the operation. In the patient who had atrial fibrillation preoperatively repeated attempts to regularize the residual postoperative fibrillation, both by medication and cardioversion, were unsuccessful.

A detailed study of different data obtained during the operation under hypothermia was made in an attempt to determine the reason for the immediate postoperative arrhythmias, but these showed no correlation with the operation time, time of circulatory arrest, cooling or rewarming time, or with the acid base values. In association with inflow occlusion all patients showed cardiac rhythm disturbances of varying types, usually nodal rhythm with ectopic ventricular beats, but there was no apparent relationship between these disturbances and the residual arrhythmias. A *tendency* was observed, however to immediate postoperative arrhythmia in patients with large central defects, and, especially those with low defects, where traumatic effects on the atrio-ventricular nodal region were often unavoidable.

P waves

Preoperatively the amplitude of the P wave, measured in mm (1 millivolt, mV = 10 mm) in *lead II* was, on the average, 1.5 in the children and 1.2 in the adults.

Postoperatively the corresponding values were 1.2 and 1 1 mm respectively Only in the children was there a significant difference (***) between the pre and postoperative values.

The *amplitude* of the P wave in *lead* V_1 was, on the average, somewhat lower both pre and postoperatively (1 0 and 0 6 mm, respectively) than in lead II but the postoperative amplitude reduction in lead V_1 was more pronounced (***)

Preoperatively the duration of the P wave in *lead II* was, on the average, 7.5 csec in the children and 8.7 in the adults.

Postoperatively the corresponding values were 6.5 and 7 7 csec, respectively The difference between the pre and postoperative values were significant for the children (***) and for the adults (**)

Only in 6 patients were preoperative signs of atrial hypertrophy observed in lead II with a P wave amplitude of 2 5 mm or more or a P wave duration of 12 csec or more.

P R interval Preoperatively the P R interval was, on the average, 15 6 csec, and at the *follow-up* examination this was significantly shorter (**) viz. 14.2 csec. The P R interval was longer than 20 csec in 13 patients (including 10 in age group C) preoperatively and in 9 patients at the follow-up examination. On the average, the adult patients showed a somewhat longer P R interval than the children.

QRS complex

In spite of large variations in the QRS complex in lead V_2, it was possible in principle to classify the different types into the four QRS patterns shown in

Fig. 3. Configuration of QRS complex in lead V

II. In 3 of these patients sinus rhythm was recorded 3 weeks, 4 months and 4 years, respectively, after the operation, but in the other 2 patients this block is still present. One 42 year old woman had a postoperative A-V block III which necessitated pacemaker therapy. Two patients had atrial fibrillation, which after medication altered to sinus rhythm 8 weeks and 12 weeks, respectively, after the operation. In the patient who had atrial fibrillation preoperatively, repeated attempts to regularize the residual postoperative fibrillation, both by medication and cardioversion, were unsuccessful.

A detailed study of different data obtained during the operation under hypothermia was made in an attempt to determine the reason for the immediate postoperative arrhythmias, but these showed no correlation with the operation time, time of circulatory arrest, cooling or rewarming time, or with the acid base values. In association with inflow occlusion all patients showed cardiac rhythm disturbances of varying types, usually nodal rhythm with ectopic ventricular beats, but there was no apparent relationship between these disturbances and the residual arrhythmias. A tendency was observed, however, to immediate postoperative arrhythmia in patients with large central defects, and especially those with low defects, where traumatic effects on the atrio-ventricular nodal region were often unavoidable.

P waves

Preoperatively the amplitude of the P wave, measured in mm (1 millivolt, mV = 10 mm) in *lead II* was, on the average, 1.5 in the children and 1.2 in the adults.

Postoperatively the corresponding values were 1.2 and 1.1 mm respectively. Only in the children was there a significant difference (***) between the pre- and postoperative values.

The *amplitude* of the P wave in *lead V_1* was, on the average, somewhat lower both pre- and postoperatively (1.0 and 0.6 mm, respectively) than in lead II, but the postoperative amplitude reduction in lead V_1 was more pronounced (***).

Preoperatively the duration of the P wave in *lead II* was, on the average, 7.5 csec in the children and 8.7 in the adults.

Postoperatively the corresponding values were 6.5 and 7.7 csec, respectively. The difference between the pre- and postoperative values were significant for the children (***) and for the adults (**).

Only in 6 patients were preoperative signs of atrial hypertrophy observed in lead II with a P wave amplitude of 2.5 mm or more or a P wave duration of 12 csec or more.

P-R interval. Preoperatively the P-R interval was, on the average, 15.6 csec, and at the *follow-up* examination this was significantly shorter (**), viz. 14.2 csec. The P-R interval was longer than 20 csec in 13 patients (including 10 in age group C) preoperatively and in 9 patients at the follow-up examination. On the average, the adult patients showed a somewhat longer P-R interval than the children.

QRS complex

In spite of large variations in the QRS complex in lead V_1, it was possible in principle to classify the different types into the four QRS patterns shown in

R rSR rsr's' rS

Fig. 5 Configuration of QRS complex in lead V

TABLE [illegible] ECG patterns in lead V before and after operation

		Before operation				
		R	SR	rsr′	S	No. of patients
After operation	R	11	2	—	—	13
	SR	5	33	5	1	44
	rsr′s	1	9	[illegible]	—	16
	S	6	4	8	14	32
No. of patients		23	48	19	15	105

Fig 5 The preoperative QRS pattern in V_1 in relation to age group heart size shunt group and right ventricular systolic pressure can be seen in Table 8. For two patients no ECG recording in V_1 was made preoperatively

Preoperatively the R pattern was seen more frequently in the children (age group A) than in the adults (age groups B and C) while the rSR pattern was somewhat more frequent among the adults. Of the two other QRS patterns, the frequency was approximately equal in the children and adults.

All four types of complex showed the greatest frequency among patients with slight cardiac enlargement, and in addition the frequency of these types was greater in patients with normal heart size than in those with pronounced enlargement.

Further all types of QRS complex, except the rSR pattern, were seen most often in shunt group 2, while the rSR pattern was somewhat more frequent in shunt group 3

The rSR pattern was of approximately equal frequency in patients with normal as in those with raised systolic right ventricular pressures, while the other QRS patterns showed a greater frequency in patients in whom this pressure was raised.

Only in children was a significant correlation (*) seen between shunt size and the amplitude of the R wave in lead V_1 At the follow up examination no significant correlation was found, however between shunt reduction and reduction of the amplitude of the R wave, either in the children or the adults.

R pattern. This is consistent with right ventricular hypertrophy and the qR and rR complexes have also been included in this type. *Preoperatively* 23 patients showed this pattern in V_1 In 10 patients (4 children and 6 adults) a qR complex was seen.

Postoperatively the ECG pattern remained unchanged in 11 patients of this group which can be seen in Table 9

rSR pattern This complex, which is described as characteristic of atrial septal defect, is considered to be due to hypertrophy and/or dilatation of the right ventricular outflow tract rather than to right intraventricular conduction delay i.e. partial right bundle branch block (Pryor et al. 1959)

Preoperatively 48 patients showed this complex in V_1

Postoperatively this type of complex persisted in 33 patients (14 children and 19 adults) and, as seen in Table 9 2 of the patients now showed an R complex, 9 an rsr's complex and 4 a normal rS complex.

In the 33 patients in whom the QRS complex was unchanged, the amplitude of R was, on the average, 10.9 mm preoperatively and 7.0 mm, i e. significantly lower (***) postoperatively The reduction of the R amplitude was more pronounced in the children than in the adults.

The ventricular activation time (VAT) in V in these patients was 6.8 csec preoperatively and 6.3 csec, i.e. significantly shorter ( ) postoperatively

rsr pattern. This QRS complex, which differs from the more typical rSR pattern mainly by its generally lower amplitude and the terminal r' wave, is probably also, however an expression of right ventricular outflow tract hypertrophy this pattern was observed *preoperatively* in 19 patients.

The rsr s' pattern persisted *postoperatively* in 6 patients, while in 5 patients a more typical rSR complex, and in 8 patients a normal rS complex, were recorded.

S pattern. This pattern, which is normal in V was seen *preoperatively* in 15 patients.

Postoperatively the pattern remained unchanged in all except one patient.

Altogether 64 patients had the same type of QRS complex postoperatively as preoperatively of which 50 were abnormal 22 patients had different types of abnormal QRS pattern on the two occasions. In 18 patients newly acquired normal QRS complexes of the rS type were observed.

The amplitude of R in V_1 in those patients who did not exhibit the rSR pattern either pre- or postoperatively was, on the average, 6.9 mm preoperatively and 4 6 mm, i. e. significantly lower (***) postoperatively the decrease in R wave amplitude being most pronounced in patients with an R complex. On the other hand, no significant change was seen in VAT which in these 72 patients was, on the average, 3.9 csec preoperatively and 3.2 csec postoperatively

Preoperatively 70 patients showed a QRS complex of type Rs in *lead* V_6, and in 33 patients this complex was of the qRs type. The amplitude of the R wave in these complexes was, on the average, 14 4 mm.

Postoperatively 55 patients showed the Rs pattern, and 41 patients a pattern of the qRs type, with an average R wave amplitude of 18.1 mm, this being significantly higher (***) than preoperatively The QRS duration in lead V_6 was, on the average, 1 0 csec shorter postoperatively than preoperatively which was due to a significant (*) reduction of the duration of the S wave from an average of 4.2 to 3.3 csec.

QRS axis. Preoperatively the mean QRS axis in the frontal plane was 81 in the children, and 89° in the adults, and the corresponding postoperative values were 75 and 71° respectively

The *postoperative* change of the mean QRS axis towards the left was significant in the adults (***) and in the children ( )

TABLE 9 ECG patterns in lead V before and after operation

	rS	6	4	8	14	32
No of patients		3	48	19	15	105

Fig 5 The preoperative QRS pattern in V_1 in relation to age group heart size shunt group and right ventricular systolic pressure can be seen in Table 8. For two patients no ECG recording in V_1 was made preoperatively

Preoperatively the R pattern was seen more frequently in the children (age group A) than in the adults (age groups B and C) while the rSR pattern was somewhat more frequent among the adults. Of the two other QRS patterns, the frequency was approximately equal in the children and adults.

All four types of complex showed the greatest frequency among patients with slight cardiac enlargement, and in addition the frequency of these types was greater in patients with normal heart size than in those with pronounced enlargement.

Further all types of QRS complex, except the rSR pattern, were seen most often in shunt group 2 while the rSR pattern was somewhat more frequent in shunt group 3

The rSR pattern was of approximately equal frequency in patients with normal as in those with raised systolic right ventricular pressures, while the other QRS patterns showed a greater frequency in patients in whom this pressure was raised.

Only in children was a significant correlation (*) seen between shunt size and the amplitude of the R wave in lead V_1 At the follow up examination no significant correlation was found, however between shunt reduction and reduction of the amplitude of the R wave either in the children or the adults.

R pattern This is consistent with right ventricular hypertrophy and the qR and rR complexes have also been included in this type. *Preoperatively* 23 patients showed this pattern in V_1 In 10 patients (4 children and 6 adults) a qR complex was seen.

Postoperatively the ECG pattern remained unchanged in 11 patients of this group, which can be seen in Table 9

rSR pattern This complex, which is described as characteristic of atrial septal defect is considered to be due to hypertrophy and/or dilatation of the right ventricular outflow tract rather than to right intraventricular conduction delay i e. partial right bundle-branch block (Pryor et al. 1959)

Preoperatively 48 patients showed this complex in V_1

Postoperatively this type of complex persisted in 33 patients (14 children and 19 adults) and, as seen in Table 9 2 of the patients now showed an R complex, 9 an rsr's complex and 4 a normal rS complex.

In the 33 patients in whom the QRS complex was unchanged, the amplitude of R was, on the average, 10.9 mm preoperatively and 7.0 mm, i.e. significantly lower (***) postoperatively The reduction of the R amplitude was more pronounced in the children than in the adults.

The ventricular activation time (VAT) in V_1 in these patients was 6 8 csec preoperatively and 6.3 csec, i.e. significantly shorter ( ) postoperatively

rsr's pattern This QRS complex, which differs from the more typical rSR pattern *mainly by its generally lower* amplitude and the terminal s wave, is probably also, however an expression of right ventricular outflow tract hypertrophy this pattern was observed *preoperatively* in 19 patients.

The rsr's pattern persisted *postoperatively* in 6 patients, while in 5 patients a more typical rSR complex, and in 8 patients a normal rS complex, were recorded

S pattern This pattern, which is normal in V_1 was seen *preoperatively* in 15 patients

Postoperatively the pattern remained unchanged in all except one patient

Altogether 64 patients had the same type of QRS complex postoperatively as preoperatively of which 50 were abnormal 27 patients had different types of abnormal QRS pattern on the two occasions. In 18 patients newly acquired *normal QRS complexes of the rS type* were observed.

The amplitude of R in V_1 in those patients who did not exhibit the rSR pattern either pre- or postoperatively was, on the average, 6.9 mm preoperatively and 4.6 mm, i.e. significantly lower (***) postoperatively the decrease in R wave amplitude being most pronounced in patients with an R complex. *On the other hand, no significant change* was seen in VAT which in these 72 patients was, on the average, 3.9 csec preoperatively and 4 2 csec postoperatively

Preoperatively 70 patients showed a QRS complex of type Rs in *lead* V_6 and in 33 patients this complex was of the qRs type. The amplitude of the R wave in these complexes was, on the average, 14 4 mm

Postoperatively 55 *patients* showed the Rs pattern, and 41 patients a pattern of the qRs type, with an average R wave amplitude of 18.1 mm, this being significantly higher (***) than preoperatively The QRS duration in lead V was, on the average, 1 0 csec shorter postoperatively than preoperatively which was due to a significant ( ) reduction of the duration of the S wave from an average of 4.2 *to* 3.3 *csec.*

QRS axis. Preoperatively the mean QRS axis in the frontal plane was 81 in the children, and 89° in the adults, and the corresponding postoperative values were 5 and 71 respectively

The *postoperative* change of the mean QRS axis *towards the left* was significant in the adults (***) and in the children (*)

Preoperatively only 14 patients (5 children and 9 adults) had a definite right axis deviation (more than + 110°) and this remained unchanged after the operation in 6 patients. No definite left axis deviation was observed, but preoperatively 4 patients showed a mean QRS axis of between 0° and 30° and this was seen in 5 patients postoperatively In cases of complete right bundle branch block, only the first 7 csec of the QRS complex were used for calculation of the mean QRS axis.

QRS duration Preoperatively the QRS duration in lead II was 8.7 csec in the children and 9 4 csec in the adults.

Postoperatively there was no significant difference in the children (8.3 csec) but significant differences were noted in the adults (**) where the value was 8.5 csec.

The QRS duration was 10 csec or shorter in 92 patients preoperatively and in 96 patients postoperatively A QRS duration of 11 csec was observed in 7 patients preoperatively and in 5 patients postoperatively A complete right bundle branch block with a QRS duration of 12 csec or more was found preoperatively in 6 adult patients, in 4 of whom this persisted postoperatively

T waves

The most pronounced T wave change occurred in the *immediate postoperative period* On the day of operation the T wave amplitude was estimated in lead II in 49 patients and was, on the average 1 9 mm in 44 of these patients the S-T segment was considered normal, and in the remaining 5 somewhat elevated. On the first day after the operation a significant change was seen (***) the T wave amplitude now being 2.9 mm, on the average, and the S-T segment initially elevated in 74 out of 100 patients in lead II This pattern persisted on the second day but a gradual depression of S-T segment and the T wave was then seen up to the sixth day after the operation, by which time its amplitude was 0 8 mm and the S-T segment normal in 79 out of 92 patients.

During the first few weeks postoperatively a pronounced change in S-T and T was seen in the precordial leads, with depression of the S-T segment and flattening or inversion of the T wave. Two weeks, on the average, postoperatively 59 patients still showed a negative or pathologically low T wave in lead V_1, with an approximately equal incidence in the children and adults.

At the follow up examination the T wave amplitude in lead II was, on the average 2.6 mm thus showing no change from the preoperative value (2.4 mm) On the other hand, a pathologically low or negative T wave was observed in precordial leads V_1—V_4 in 42 patients (21 children and 21 adults) and in lead V_6 in 13 patients. Thirty of these 42 patients performed exercise tests postoperatively In half of them the T wave, which was inverted at rest, showed some normalization in the standing position during the orthostatic test and on deep inspiration. In all patients the T wave over the precordium gradually became normal with increasing work loads. This is an ECG reaction which may be seen in patients with previous

perimyocardial damage, and it has therefore been called "status post myocardial lesion" (Areskog and Hallén, 1964)

Discussion

The incidence of atrial fibrillation in ASD sec varies, but according to Wood (1962) who has discussed the haemodynamic effects and prognostic importance of atrial fibrillation in this condition, it is correlated particularly with age. Thus in the present series, of which only 4 patients were above 50 years of age, it was not surprising to find only one patient with atrial fibrillation — the oldest patient. In this patient the fibrillation was still resistant to therapy after the operation, and, together with pronounced cardiac enlargement, as seen roentgenologically it probably expressed an irreversible myocardial lesion.

In three patients with residual postoperative arrhythmia of the high-grade A-V block type, the long term prognosis is uncertain and in patients with uncomplicated ASD sec, a postoperative high grade A V block is a complication which may worsen the outlook considerably compared with the preoperative prognosis.

The postoperative arrhythmia in atrial septal defect is considered to be due to surgical trauma according to Popper et al. (1962) the manipulations especially in the vicinity of the A V node have an arrhythmia-inducing effect, and these authors state that apart from such factors the incidence of arrhythmia is only influenced by age

In the present series 57 patients (53 %) showed arrhythmia at some time during the first week postoperatively This is a rather higher figure than that of Popper et al. (1962) who found a total arrhythmia frequency of 43 % among a series of 126 secundum defects in their patients, however extracorporeal circulation was used, and from this aspect the two series are not entirely comparable. As in Popper series, in which the patients were, on the average, somewhat younger the incidence of arrhythmia in the present series increased with age.

The immediate postoperative supraventricular arrhythmia was, in most cases, of nodal origin. Since this arrhythmia was regular and of normal frequency it caused the patient no discomfort. This arrhythmia, which can be caused by temporary oedema in the atrio-ventricular nodal region (Gomez et al. 1962) ppeared to change to sinus rhythm spontaneously regardless of whether the patient received digitalis or not. Digitalis medication was not given as a routine preoperatively

Serious postoperative arrhythmias in ASD sec have been described by among others, Sellors (1961) and Derra et al. (1965) Derra et al. reported 2 cases of total A V block among a series of 700 surgically repaired secundum defects these two patients showed spontaneous regression within 2 months of the operation, however

Especially in the adults, postoperative arrhythmia often prolonged the period of hospitalization considerably and the increasing risk of arrythmia in ASD sec with advancing age, both with and without operation, indicates early surgery

The preoperative ECG changes in ASD sec have been discussed greatly especially as regards the correlation between ECG pattern and haemodynamics, and the aetiology of the typical rSR complex in lead V_1 Pryor Woodward and Blount (1959) in a study of 100 surgically closed secundum defects, found no applicable correlation between the QRS axis or height of R in lead V_1 and either the pulmonary arterial pressure, total pulmonary resistance or pulmonary flow A lack of correlation between ECG and haemodynamics has also been shown by Walker et al. (1955) and Barboza et al. (1958) *inter alia* but De Oliveira and Zimmerman (1958) and Lee and Scherlis (1962) on the other hand, found some correlation between the QRS pattern in lead V_1 and the magnitude of the left to-right shunt. In the present series, however a significant correlation (*) between shunt size and the amplitude of the R wave in lead V_1 was seen only in children. At the follow up examination no significant correlation was found between shunt reduction and reduction of the amplitude of the R wave, either in the children or the adults.

Cabrera and Monroy (1952) and Sodi Pallares and Marsico (1955) considered that incomplete right bundle-branch block (IRBBB) in atrial septal defect was due to diastolic overloading of the right ventricle, while on the contrary Walker et al. (1956) Blount et al. (1957) Silverblatt et al. (1957) and, in particular De Oliveira and Zimmerman (1958) did not regard IRBBB as representing conduction delay in the right branch, but rather the presence of anatomical right ventricular dilatation and/or selective hypertrophy of the right ventricular outflow tract (crista supraventricularis) resulting in delayed activation of this tract. Both groups of authors considered, however that right ventricular dilatation rather than right ventricular hypertrophy was typical in ASD patients with large left to-right shunts and essentially normal right ventricular pressures.

The preoperative ECG changes in this series agreed in the main with those described in uncomplicated ASD sec by Pryor et al. (1959) and Loogen et al. (1961) among others.

After closure of an atrial septal defect, the diastolic overloading of the right ventricle disappears. The dilatation of the right ventricle decreases, as also does the hypertrophy in the right ventricular outflow tract. As a result the amplitude of the R wave in lead V_1 is reduced, and the mean QRS axis changes towards the left (Davies et al 1960 Loogen et al. 1961) The regression of the preoperative ECG abnormalities is considered to indicate that the rSR pattern in lead V_1 is caused by dilatation and/or hypertrophy rather than intraventricular conduction delay since this can hardly be affected by the operation (De Oliveira and Zimmerman 1958 Davies et al. 1960) The P wave also decreases in both amplitude and duration after the operation (Sanchez-Cascos et al. 1963)

In the present series only six patients showed definite signs of atrial hypertrophy which seems a low figure in view of the previous finding of a frequency up to 30 % in ASD sec (Sánchez-Cascos et al. 1963) Only among the children were

significant (***) changes observed in the amplitude and duration of the P wave in lead II among the adults no change in amplitude was seen, but the duration was significantly (**) shorter. The postoperative decrease in the P wave must be an expression of flow reduction in the right atrium, even though no relationship was found preoperatively between shunt size and P wave pattern in lead II or V_1.

On comparing the pre- and postoperative QRS complexes, it was found that the QRS pattern in V was the same on both occasions in no fewer than 64 patients, and in 50 of the cases this pattern was considered to be pathological. Postoperatively a tendency towards normalization of the QRS pattern in V_1 was observed, but newly acquired normal QRS complexes of the rS type with an R/S ratio of less than 1 were seen in only 18 patients. Thus even though in most cases the *type* of QRS pattern remained unchanged, the *degree* of abnormality had decreased, especially as regards the amplitude of R or R' in lead V. In the 33 patients with the same characteristic secundum complex of the rSR' type in V pre- and postoperatively the activation time was only almost significantly shorter ( ) postoperatively than preoperatively while the amplitude was highly significantly lower (***). This may indicate that in these cases the amplitude reduction corresponded to regression of the hypertrophy and/or dilatation in the right ventricular outflow tract while, on the other hand, a residual QRS pattern with a split complex may point to a congenital abnormality in the right bundle branch. Thus also corresponds to changes over the left ventricle (lead V_6) where a more pronounced *increase* (***) of the R wave amplitude was seen, as a sign of increased left ventricular activity while, on the other hand, the reduction of the preoperatively wide S wave, probably caused by right ventricular conduction delay was less pronounced (*).

A postoperative pathological QRS complex in V_1 differing more in degree than in type from the *preoperative* pattern was not thus an expression of a residual shunt, even though in some isolated cases the reduction in amplitude of the R wave was not especially pronounced.

Elevation of the S-T segment and inversion of the T wave in the immediate postoperative period are usually seen after open heart surgery (Areskog and Hallén, 1964). The S-T segment becomes normal after about a week, while the T wave change in the precordial leads may persist for a very long time. In the present series, at the follow-up examination pathological T wave changes were recorded in precordial leads V_1—V in 42 patients and in lead V_6 in 13 patients. These T wave abnormalities, probably caused by perimyocardial disturbances during the operation, were of the "status post myocardial lesion" type, and gradually became normal during exercise tests. Similar types of ECG reactions with normalization of negative T waves during and after exercise have been described in myocardial lesions caused by *infarction* (Stokes 1946, Söderholm et al. 1962, Areskog and Hallén 1964) and in cardiomyopathy in Friedreich's ataxia (Thorén 1964).

and occur after open heart surgery not only in ASD sec but also in other cases. In approximately half of the patients in the present series some normalization of the T wave was observed on deep inspiration. A similar ECG response in healthy persons has been described by Blackman and Kuskin (1964) who considered that such a change in the T wave could be explained by the change in position of the heart during deep inspiration. In a number of cases where the part of the left lung covering the anterior region of the heart (the "cardiac notch") was poorly ventilated, Blackman and Kuskin recorded T waves, in leads V_3—V_4 of the type also seen in direct epicardial recording. On deep inspiration the distance between the heart and the thoracic wall is increased by the air filled lung which is a poor conductor of electrical currents, and the T wave amplitude changes.

In cases of surgically repaired ASD sec there is no definite reason to assume that the normalization of the T wave during exercise is due to changes in the myocardial metabolism or improved coronary perfusion resulting from vasodilatation as has been discussed in connection with S-T and T alteration during exercise after myocardial infarcts. Hyperactivity of the sympathetic nervous system may explain depression and/or inversion of the T wave which changes can be normalized by the use of ganglia blocking media (Linderholm et al. 1962, Thorén 1964). This was not tested in the present series. After a thoracotomy the occurrence of small pleural adhesions can probably be assumed which could make air filling of the "cardiac notch" difficult, and contribute to the occurrence of T wave changes especially in those cases where some normalization of the T wave on deep inspiration has been observed. These postoperative T wave abnormalities, which may thus be caused by a vegetative or functional mechanism are considered to be benign in character and are not to be regarded as unfavourable.

Summary

ECG studies were made on 107 patients with ASD sec before and after operation. Preoperatively one patient showed atrial fibrillation. Postoperative arrhythmia occurred in 57 patients but 8 days after the operation this was observed in only 21 patients. A tendency to immediate postoperative arrythmia was seen especially in patients with large, low ASD sec. Five patients showed arrhythmia at the follow up examination, but only 3 patients at a later examination two of these three patients had an A V block II and the third an A V block III the latter requiring pacemaker therapy.

No relationship was found between shunt magnitude and the duration of amplitude of the P wave. Only 6 patients showed preoperative signs of atrial hypertrophy.

The preoperative ECG findings in this series were of the type usually described in ASD sec. In lead V_1 four principal types of QRS complex were distinguished. 50 patients showed the same pathological QRS complex postoperatively as preoperatively thus being of the "ASD sec" type, with an rSR pattern, in 33 of these patients. The QRS

complex was evaluated as normal in 15 patients preoperatively and 3? patients postoperatively. In this series a significant correlation ( ) between shunt size and the amplitude of the R wave in lead V was seen only in children. At the follow-up examination, however no significant correlation was found between shunt reduction and reduction of the amplitude of the R wave, either in the children or the adults.

Preoperatively only 14 patients showed a definite right axis deviation (more than + 110°). No definite left axis deviation (less than —30°) was seen. The postoperative change of the mean QRS axis towards the left was more marked in the adults than in the children.

Postoperatively the QRS duration was shorter in the adults but, on the average, unchanged in the children. Complete right bundle branch block with a QRS duration of 12 csec or more occurred preoperatively in [illegible] adult patients.

During the immediate postoperative period the S-T segment and T wave showed changes of the type usually seen in pericarditis. At the follow-up examination there was a residual pathological T wave in lead V_4 in 42 patients. In 30 patients who performed work tests, normalization of the T wave, which at rest was inversed, was observed during and after exercise. The reason for this "status post myocardial lesion" reaction is discussed and is considered to be of no functional importance. This pathological T wave at rest though observed for a long period after the operation, should not thus be regarded as unfavourable.

and occur after open heart surgery not only in ASD sec but also in other cases. In approximately half of the patients in the present series some normalization of the T wave was observed on deep inspiration. A similar ECG response in healthy persons has been described by *Blackman and Kuskin (1964)* who considered that such a change in the T wave could be explained by the change in position of the heart during deep inspiration. In a number of cases where the part of the left lung covering the anterior region of the heart (the "cardiac notch") was poorly ventilated Blackman and Kuskin recorded T waves in leads V_2—V_4 of the type also seen in direct epicardial recording. On deep inspiration the distance between the heart and the thoracic wall is increased by the air filled lung which is a poor conductor of electrical currents, and the T wave amplitude changes.

In cases of surgically repaired ASD sec there is no definite reason to assume that the normalization of the T wave during exercise is due to changes in the myocardial metabolism or improved coronary perfusion resulting from vasodilatation as has been discussed in connection with S-T and T alteration during exercise after myocardial infarcts. Hyperactivity of the sympathetic nervous system may explain depression and/or inversion of the T wave, which changes can be normalized by the use of ganglia blocking media (Linderholm et al. 1962 Thorén 1964). This was not tested in the present series. After a thoracotomy the occurrence of small pleural adhesions can probably be assumed which could make air filling of the cardiac notch" difficult, and contribute to the occurrence of T wave changes especially in those cases where some normalization of the T wave on deep inspiration has been observed. These postoperative T wave abnormalities, which may thus be caused by a vegetative or functional mechanism, are considered to be benign in character and are not to be regarded as unfavourable.

summarized in Tables 10 and 11 and Figures 6—8 Some individual values, either preoperative or for the follow up examination were not obtainable, and for this reason the number of values sometimes varies in the different tables and figures.

Oxygen saturation

Left atrium In 71 patients the oxygen saturation in the left atrium was recorded, the value obtained being, on the average, 96 % In 3 patients the value was below normal 2 patients with a value of 90 % were found on operation to have large low defects with prerequisite conditions for a right to-left shunt. These patients had no pulmonary hypertension nor cyanosis. In the third patient the oxygen saturation was 90 % in the left atrium, brachial artery and pulmonary vein This patient also showed moderately pronounced pulmonary hypertension.

Superior vena cava (Fig 6) *Preoperatively* the oxygen saturation in the superior vena cava was, on the average 65 % In 18 patients with anomalous

enous return to the superior vena cava, the saturation values were obtained above the entrance of the pulmonary veins, and these were found to be within the normal range in all cases except one.

At recatheterization the oxygen saturation in the superior vena cava was, on the average, 69 %; this was significantly (***) higher than before the operation.

Pulmonary artery (Fig. 7). *Preoperatively* the oxygen saturation in the pulmonary artery was, on the average, 84 % and varied between 80 % and 90 % in 82 patients. In 7 patients with a very high left-to-right shunt this value was 90 % or more. In 8 patients the oxygen saturation was lower than 80 %. In two girls with particularly low values (72 % and 68 %) the left-to-right shunt was estimated to be about 30 %. The difference in oxygen saturation between the pulmonary artery and superior vena cava in the entire series was, on the average, 19 %.

On *recatheterization* the oxygen saturation in the pulmonary artery was, on

the average 70 % In 80 cases the values varied between 65 % and 75 % The saturation difference between the pulmonary artery and superior vena cava was, on the average, 1 % No signs of a residual left to-right shunt were observed in any of the 107 patients. In 5 patients with a somewhat high oxygen saturation (77—78 %) however the saturation difference between the pulmonary artery and superior vena cava was only 3 %. In 8 patients rather low values of between 58 % and 64 % were noted.

Left to-right shunt, heart volume and systolic right ventricular pressure

Preoperatively the *left-to-right shunt* was, on the average 61 % of the pulmonary blood flow in two patients this value was unobtainable. No residual shunts were found at the follow-up examination. The distributions of patients in the different shunt and X ray groups according to age groups is seen in Table 12. Eighteen patients (10 children and 8 adults) belonged to shunt group 1 The frequency of children (age group A) in shunt groups 2 and 3 was approximately equal, while the young adults (age group B) showed a greater frequency in shunt group 2 and the older adults (age group C) in shunt group 3.

A normal *heart volume* was seen in a total of 19 patients, 10 of whom were young adults in shunt group 2. Slight heart enlargement was observed in just over half i e. 58 of the patients, with a somewhat greater frequency in the children than in the adults. Moderate or pronounced heart enlargement was seen in 28 patients with predominance among the children, and older adults of shunt group 3

The *systolic right ventricular pressure* was 30 mm Hg or more in 61 out of 107 patients In only 6 patients was this 50 mm Hg or more As seen in Table 13 normal systolic right ventricular pres-

sures were more frequent in children than in adults, and in shunt groups 1 and normal values for this pressure were just as frequent as raised values. In shunt group 3, on the other hand, raised systolic right ventricular pressures were most frequent, especially among the older adults. In many cases there was some relationship between size of left-to-right shunt and heart volume.

In the present series, however, no significant correlation was found between

Table 13 Distribution of patients in shunt and age groups according to RV systolic pressure.

Shunt group	RV systolic pressure, mm Hg	Age group A	B	C	Total
1	< 30	5	1	2	8
	> 30	5	3	1	9
2	< 30	13	7	3	23
	> 30	9	10	2	1
3	< 30	7	2	1	10
	> 30	11	6	14	31

the size of the left to-right shunt, expressed in % of the pulmonary blood flow and the preoperative roentgenological heart volume, expressed in ml/m² body surface area in any of the age groups. In the older adults, however there was a significant correlation (*) between shunt size and systolic right ventricular pressure but this was not found in the other two age groups.

At the follow up examination no statistically certain correlation was found between shunt reduction and reduction of the relative heart volume or systolic right ventricular pressure, in the different age groups.

Intracardiac and intravascular pressures

The pressure results obtained on cardiac catheterization at rest before and after operation are summarized in Fig 8

Right atrium (RA) Preoperatively the mean pressure in the right atrium was, on the average 3 7 mm Hg In 24 patients, including 12 children a mean pressure of over 5 mm Hg was found.

At *recatheterization* the mean pressure was 2.0 mm Hg In 72 patients the pressure was lower than before the operation in 17 patients it was unchanged and in 16 patients somewhat higher 6 patients showed a mean pressure of more than 5 mm Hg The mean pressure in RA, both preoperatively and at recatheterization, was somewhat higher in the children than in the older adults. This pressure was significantly (**) lower postoperatively than preoperatively

Right ventricle (RV) Preoperatively the systolic pressure in the right ventricle was moderately raised 32 mm Hg [illegible] patients showed a pressure of 30 mm Hg or higher this being somewhat more frequent in adults than in children. In 6 patients this pressure was 50 mm Hg or higher Three of these had mild valvular pulmonary stenosis, which in two cases necessitated valvulotomy at the operation. In the third patient the systolic right ventricular pressure was still 50 mm Hg on recatheterization.

The end-diastolic pressure was, on the average, 2 8 mm Hg i e. normal and the diastolic pressure gradient between the right atrium and right ventricle was 0.9 mm Hg

On *recatheterization* the systolic right ventricular pressure was normal 24 mm Hg In 87 patients this pressure was now lower than preoperatively In one patient it was unchanged and in 16 patients somewhat higher In 16 patients (8 children 5 young adults and 3 older adults) the pressure remained at 30 mm Hg or higher

The end-diastolic pressure was essentially unchanged, 2.3 mm Hg

The systolic right ventricular pressure was significantly lower (***) on re

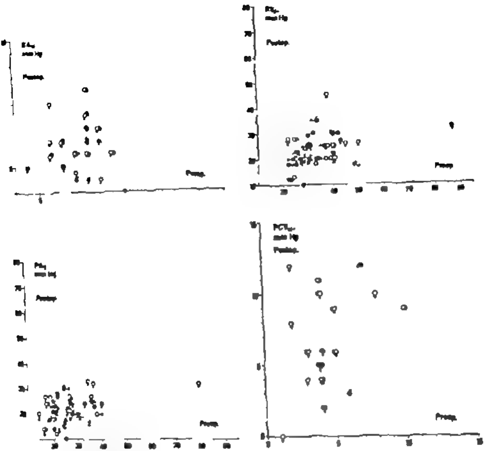

Fig. 8. Mean right atrial (RA) and pulmonary capillary venous (PCV) pressures, and systolic pressure in right ventricle (RV) and pulmonary artery (PA) in mm Hg before and after operation. Symbols as in Fig. 6.

catheterization than preoperatively. Neither before operation nor at recatheterization was there any definite sex or age difference with regard to the systolic or diastolic right ventricular pressures.

Pulmonary artery (PA). Preoperatively the systolic pressure in the pulmonary artery was, on the average, 26 mm Hg. In 27 patients this pressure was 30 mm Hg or higher, this value being somewhat more frequent in adults than in children. Only 3 patients had pulmonary hypertension, with systolic PA pressure of 50 mm Hg or more. In 2 of these patients this pressure was 50 mm Hg, and in 1 patient 80 mm Hg.

The diastolic and mean pressures were normal, with average values of 9 mm and 16 mm Hg, respectively.

The systolic *pressure gradient* between RV and PA was, on the average, 7 mm Hg. No definite relationship was found

TABLE 13 Distribution of patients in shunt and age groups according to RV systolic pressure.

Shunt group	RV systolic pressure, mm Hg	Age group A	B	C	Total
1	< 30	5	1	2	8
	> 30	5	3	1	9
2	< 30	13	7	3	23
	> 30	9	10	2	21
3	< 30	7	2	1	10
	> 30	11	6	14	31

the size of the left-to-right shunt expressed in % of the pulmonary blood flow and the preoperative roentgenological heart volume, expressed in ml/m² body surface area, in any of the age groups. In the older adults, however there was a significant correlation (*) between shunt size and systolic right ventricular pressure, but this was not found in the other two age groups.

At the follow-up examination no statistically certain correlation was found between shunt reduction and reduction of the relative heart volume or systolic right ventricular pressure, in the different age groups.

Intracardiac and intravascular pressures

The pressure results obtained on cardiac catheterization at rest before and after operation are summarized in Fig 8.

Right atrium (RA) *Preoperatively* the mean pressure in the right atrium was on the average, 3 7 mm Hg In 24 patients, including 12 children, a mean pressure of over 5 mm Hg was found.

At *recatheterization* the mean pressure was 2.0 mm Hg In 72 patients the pressure was lower than before the operation in 17 patients it was unchanged and in 16 patients somewhat higher 6 patients showed a mean pressure of more than 5 mm Hg The mean pressure in RA, both preoperatively and at recatheterization, was somewhat higher in the children than in the older adults. This pressure was significantly (**) lower postoperatively than preoperatively

Right ventricle (RV) Preoperatively the systolic pressure in the right ventricle was moderately raised, 32 mm Hg 63 patients showed a pressure of 30 mm Hg or higher this being somewhat more *frequent in adults than in children.* In 6 patients this pressure was 50 mm Hg or higher Three of these had mild valvular pulmonary stenosis, which in two cases necessitated valvulotomy at the operation. In the third patient the systolic right ventricular pressure was still 50 mm Hg on recatheterization.

The end-diastolic pressure was, on the average, 2 8 mm Hg, i.e. normal, and the diastolic pressure gradient between the right atrium and right ventricle was 0.9 mm Hg

On *recatheterization* the systolic right ventricular pressure was normal, 24 mm Hg In 87 patients this pressure was now lower than preoperatively In one patient it was unchanged and in 16 patients somewhat higher In 16 patients (8 children, 5 young adults and 3 older adults) the pressure remained at 30 mm Hg or higher

The end-diastolic pressure was essentially unchanged, 2.3 mm Hg

The systolic right ventricular pressure was significantly lower (***) on re-

pect completely normal conditions of pressure and oxygen saturation. If, on recatheterization, pathological changes are found, these may be attributable either to a residual left-to-right shunt, i.e. incomplete closure of the defect, or to incomplete regression of preoperative pathological conditions: this latter in turn may be due either to the fact that these conditions are not reversible, or may indicate a too short observation period after operation. In the present series no residual shunts were found, and the observation period between operation and follow-up examination was sufficiently long to allow a return to normal haemodynamic conditions.

It is always difficult to compare different clinical series. On evaluation of the present preoperative clinical and haemodynamic data certain differences were found from the results in atrial septal defect reported previously by Jonsson et al. (1957), Kjellberg et al. (1959), Davidsen (1960), Bedford (1961), Reindell et al. (1962), Storstein and Efskind (1963), and others: this can probably be explained by differences in the composition of the material with respect to age, types of defect and complicating abnormalities. With only few exceptions, the present series consisted by chance of patients with haemodynamically uncomplicated atrial septal defects of the secundum type and can probably be regarded as representative of patients with this disease up to the age of 60 years.

When cyanosis occurs in atrial septal defect of the secundum type, the reason is usually suspected to be a right-to-left shunt caused by increase in resistance in the pulmonary circulation (Besterman 1961), in which case closure of the defect is contraindicated.

Woolf (1963) found, however, that raised pressure in the pulmonary artery in patients with ASD could give rise to oedema in the alveolar-capillary membrane and reduced arterial oxygen saturation. This could probably explain the slight cyanosis noted preoperatively in one patient with moderately pronounced pulmonary hypertension of the hyperkinetic type and with reduced oxygen saturation in the pulmonary veins. After operation, performed with the aid of extracorporeal circulation, normalization of the pressures was observed, and normal saturation values, which indicates that a reversible change of the above type may have taken place. It is evident from the case described here that other causes for cyanosis in ASD sec. can sometimes be demonstrated, which may mean that the patient can undergo operation with a good result.

Kjellberg et al. (1959) found that low posteriorly situated secundum defects, with the opening of the inferior vena cava directed towards the left atrium, could give rise to insignificant right-to-left shunts with reduced oxygen saturation in the left atrium, even though the pressure there was higher than in the right atrium. This was probably the explanation for the reduced oxygen saturation in the left atrium in two children with a normal pulmonary venous saturation, in whom maximal low posteriorly situated defects were found at operation.

It was of interest to note in the present series that the oxygen saturation in the superior vena cava lay at a normal level

between magnitude of shunt and pressure gradient. The pressure gradient is assessed from withdrawal curves, except in 8 patients with a technically negative gradient. In 64 out of 103 patients the systolic gradient between RV and PA was less than 10 mm Hg in 25 patients this gradient lay between 10 and 20 mm Hg and in only 6 patients was it above 20 mm Hg In three patients with gradients of 31 36, and 40 mm Hg, mild pulmonary valvular stenosis was present.

At *recatheterization* the systolic PA pressure was, on the average, 22 mm Hg In 68 patients this pressure was now lower in 3 patients it was unchanged and in 31 patients somewhat higher in 14 of these latter patients a value of 30 mm Hg or more was noted The systolic pressure in the pulmonary artery was, on the average, almost significantly (*) lower postoperatively than before operation.

The diastolic and mean pressures were 8 mm and 13 mm Hg, respectively

The systolic *pressure gradient* between RV and PA was now on the average, 2 mm Hg In 77 patients the gradient was lower than before the operation in 5 it was unchanged and in 16 patients somewhat higher This gradient was significantly (**) lower on recatheterization than preoperatively

Pulmonary capillary venous (PCV) pressure Preoperatively the mean PCV pressure was normal being on the average 8 4 mm Hg The mean pressure was somewhat lower in older than in young patients.

On *recatheterization* this mean pressure was found on the average to be unchanged 6.5 mm Hg In 37 patients, however the value was higher than preoperatively while in 8 it was unchanged and in 29 lower The mean pressure was also now on the average, somewhat lower in older and young adults than in children

There was no statistically significant change in the mean PCV pressure after the operation.

Left atrium (LA) Preoperatively the mean pressure in the left atrium was recorded in 76 patients and was found, on the average, to be 5 2 mm Hg, and somewhat higher in children and young adults than in the older persons. The difference in mean pressure between left and right atrium was, on the average 1.5 mm Hg and the corresponding value for PCV and left atrium 1 2 mm Hg The difference in mean pressure between PCV and right atrium was 2.7 mm Hg before the operation and 4.5 mm Hg at the follow up examination.

Left ventricle (LV) Preoperatively the left ventricular pressure was recorded in 47 patients this was found to be, on the average, 98 mm Hg in children, 102 mm Hg in young adults and 117 mm Hg in the older adults. The end-diastolic pressures in these three age groups were 4 9 4 9 and 5 8 mm Hg respectively There was no end-diastolic pressure difference between left atrium and left ventricle. The difference in end-diastolic pressure between the left and right ventricles was, on the average 2 3 mm Hg

Discussion

After successful surgical repair of an uncomplicated atrial septal defect of the secundum type there is reason to ex

pect completely normal conditions of pressure and oxygen saturation. If on recatheterization, pathological changes are found, these may be attributable either to a residual left-to-right shunt, i.e. incomplete closure of the defect, or to incomplete regression of preoperative pathological conditions: this latter in turn may be due either to the fact that these conditions are not reversible, or may indicate a too short observation period after operation. In the present *series no residual shunts were found*, and the observation period between operation and follow-up examination was sufficiently long to allow a return to normal haemodynamic conditions.

It is always difficult to compare different clinical series. On evaluation of the present preoperative clinical and haemodynamic data certain differences were found from the results in atrial septal defect reported previously by Johnson et al. (1957), Kjellberg et al. (1959), Davidsen (1960), Bedford (1961), Rendell et al. (1962), Sternstein and Edlund (1963) and others: this can probably be explained by differences in the composition of the material with respect to age, types of defect and complicating abnormalities. With only few exceptions, the present series consisted by balance of patients with haemodynamically uncomplicated atrial septal defects of the secundum type, and can probably be regarded as representative of patients with this disease up to the age of 60 years.

When cyanosis occurs in atrial septal defect of the secundum type, the reason is usually suspected to be a right-to-left shunt caused by increase in resistance in the pulmonary circulation (Besterman 1961) in which case closure of the defect is contraindicated.

Woolf (1963) found, however, that raised pressure in the pulmonary artery in patients with ASD could give rise to oedema in the alveolar-capillary membrane and reduced arterial oxygen saturation. This could probably explain the *slight cyanosis noted preoperatively* in one patient with moderately pronounced pulmonary hypertension of the hyperkinetic type and with reduced oxygen saturation in the pulmonary veins. After operation, performed with the aid of extracorporeal circulation, normalization of the pressures was observed, and normal saturation values, which indicates that a reversible change of the above type may have taken place. It is evident *from the case described here that other causes for cyanosis in ASD sec. can sometimes be demonstrated*, which may mean that the patient can undergo operation with a good result.

Kjellberg et al. (1959) found that low posteriorly situated secundum defects, with the opening of the inferior vena cava directed towards the left atrium, could give rise to insignificant right-to-left shunts with reduced oxygen *saturation in the left atrium*, even though the pressure there was higher than in the right atrium. This was probably the explanation for the reduced oxygen saturation in the left atrium in two children with a normal pulmonary venous saturation, in whom maximal low posteriorly situated defects were found at operation.

It was of interest to note in the present series that the oxygen saturation in the superior vena cava lay at a normal level

between magnitude of shunt and pressure gradient. The pressure gradient is assessed from withdrawal curves, except in 8 patients with a technically negative gradient. In 64 out of 103 patients the systolic gradient between RV and PA was less than 10 mm Hg, in 25 patients this gradient lay between 10 and 20 mm Hg, and in only 6 patients was it above 20 mm Hg. In three patients with gradients of 31, 36 and 40 mm Hg mild pulmonary valvular stenosis was present.

At *recatheterization* the systolic PA pressure was, on the average 22 mm Hg. In 68 patients this pressure was now lower, in 3 patients it was unchanged and in 31 patients somewhat higher; in 14 of these latter patients a value of 30 mm Hg or more was noted. The systolic pressure in the pulmonary artery was, on the average, almost significantly (*) lower postoperatively than before operation.

The diastolic and mean pressures were 8 mm and 13 mm Hg, respectively.

The systolic *pressure gradient* between RV and PA was now, on the average 2 mm Hg. In 77 patients the gradient was lower than before the operation, in 5 it was unchanged and in 16 patients somewhat higher. This gradient was significantly (**) lower on recatheterization than preoperatively.

Pulmonary capillary venous (PCV) pressure. Preoperatively the mean PCV pressure was normal, being on the average 6.4 mm Hg. The mean pressure was somewhat lower in older than in young patients.

On *recatheterization* this mean pressure was found, on the average, to be unchanged, 6.5 mm Hg. In 37 patients however the value was higher than preoperatively, while in 8 it was unchanged and in 29 lower. The mean pressure was also now, on the average, somewhat lower in older and young adults than in children.

There was no statistically significant change in the mean PCV pressure after the operation.

Left atrium (LA). Preoperatively the mean pressure in the left atrium was recorded in 76 patients and was found, on the average, to be 5.2 mm Hg and somewhat higher in children and young adults than in the older persons. The difference in mean pressure between left and right atrium was, on the average, 1.5 mm Hg, and the corresponding value for PCV and left atrium 1.2 mm Hg. The difference in mean pressure between PCV and right atrium was 2.7 mm Hg before the operation and 4.5 mm Hg at the follow up examination.

Left ventricle (LV). Preoperatively the left ventricular pressure was recorded in 47 patients; this was found to be, on the average, 98 mm Hg in children, 102 mm Hg in young adults and 117 mm Hg in the older adults. The end-diastolic pressures in these three age groups were 4.9, 4.9 and 5.8 mm Hg, respectively. There was no end-diastolic pressure difference between left atrium and left ventricle. The difference in end-diastolic pressure between the left and right ventricles was, on the average, 2.3 mm Hg.

Discussion

After successful surgical repair of an uncomplicated atrial septal defect of the secundum type, there is reason to ex

higher in the young than in the older adults, which is in agreement with investigations in normal persons according to Granath et al. (1964). It is always difficult in clinical series to assess the significance of small pressure differences, especially where mean pressures and filling pressures are concerned. The mean PCV pressure was, however, the only pressure which showed no significant change, this remaining at a normal level at the follow-up examination. Preoperatively the mean PCV pressure was, on the average, 1 mm higher than the mean pressure in the left atrium, and therefore this pressure difference was probably of approximately equal magnitude postoperatively also. In that case the postoperative pressure difference between the atria will be normal, i.e. approximately 3 mm Hg, which then means normal filling pressures in the respective ventricles. This also means that preoperatively the filling pressure was raised for the right ventricle and, in many cases, was lowered for the left, compared with normal values. The normal pressure difference between the left and right atrium depends on the difference in resistance between the left and right ventricular circulation, the left ventricle requiring a higher filling pressure than the right ventricle. Also, according to Berglund (1955), at the same filling pressure the stroke volume of the right ventricle exceeds that of the left ventricle. The normal pressure difference between the atria is influenced by the septal defect, and when this defect is sufficiently large, pressure equilibration takes place which is clearly unphysiological in consideration of the normal filling pressure and functional mechanism of both the right and the left ventricle. These pressure relationships form prerequisite conditions for the occurrence of a left-to-right shunt, but they may also mean some reduction of the filling of the left ventricle and the systemic flow.

The postoperative pressure reduction was most pronounced in the right ventricle (***), right atrium (**) and in the pulmonary artery (*), while the mean PCV pressure showed no significant change, and therefore the pressure gradient across the pulmonary capillary bed remained essentially unaltered and independent of the pulmonary blood flow. However, among the older patients with large left-to-right shunts preoperatively, there was a tendency towards higher mean PCV pressures postoperatively. This was probably an expression of increased filling pressure of the left ventricle.

The frequency of pulmonary hypertension reported in ASD sec. varies considerably, due mainly to differences in definition and in the composition of the series of patients described. Besterman (1961) found a frequency of 16 % with systolic PA pressure equal to or higher than 50 mm Hg, among a series of 225 ASD sec. Derra et al. (1965) found from literature reports a frequency varying between 13 and 25 %. Only 3 patients (2.6 %) in the present series had pulmonary hypertension, which thus seems a remarkably low frequency. The frequency of pulmonary hypertension increases with advancing age, and in addition, recurrent upper respiratory infections probably play an important role (Besterman

at the follow up examination, and was significantly higher (***) than preoperatively The preoperative value, which lay at the lower normal limit may thus have been an expression of increased peripheral utilization of the oxygen content of the blood, which may be associated with so called hypokinetic circulation.

Jonsson et al. (1957) in particular have discussed the relationship between the size of the left-to-right shunt and the degree of roentgenological cardiac enlargement as an expression of the adaptation of the right heart to the shunt. Davidsen (1960) and Derra et al. (1965) and also Zaver and Nadas (1965) have reported this relationship Kjellberg et al (1959) Reindell et al. (1962) and Zaver and Nadas (1965) found, however a normal heart volume in 8—12 % of their cases, thus being *somewhat more frequent in children and* young adults. According to Bedford et al. (1957) increasing age is accompanied by a tendency to increasing heart volumes. Davidsen (1960) found that pronounced cardiac enlargement above that which can be explained by the shunt, was prognostically unfavourable, and was usually an expression of myocardial and/or valvular disorders.

A normal heart volume preoperatively need not, however exclude the existence of a relationship between shunt magnitude and heart size. The shunt volume involves the right atrium and ventricle, where a large shunt volume should cause more *pronounced enlargement* than a small volume, under conditions similar in other respects (myocardial function flow resistance) Conceivably therefore, the total relative heart volume could be normal in such cases where the left ventricle, perhaps because of lack of physical training, is relatively smaller than normally (Jonsson 1966) After the operation a volume reduction may then be an expression of flow reduction in the right heart.

At the follow-up examination, however no statistically certain correlation was found, in the present series, between shunt reduction and reduction of the relative heart volume or systolic right ventricular pressure, in the different age groups.

Some overrepresentation of large left-to-right shunts in older patients can be explained by the fact that these patients had had symptoms which led to cardiological investigation.

The postoperative pressure reaction at rest in the pulmonary circulation was in accordance with previous *findings*, and involved a reduction from slightly raised or high normal pressure levels to normal values (Kirklin et al. 1956) This can be considered to agree with the haemodynamic mechanism in patients with uncomplicated secundum defects, and can be explained by the hyperkinetic effect of the left-to-right shunt which results in a pressure increase to high normal values but not usually to values that are pathologically raised

The pressure difference between the atria in uncomplicated atrial septal defect has been described by Kjellberg et al. (1959) among others, and in the present series this was, on the average, 1.5 mm Hg The mean pressure in both the right and the left atrium and also the mean PCV pressure were somewhat

Haemodynamic findings at rest and during exercise in 51 patients at follow up examination

In 51 patients pressure and flow determinations were made both at rest and during exercise on recatheterization.

These patients (5 girls and 6 boys in age group A, 18 women and 5 men in age group B, and 15 women and 2 men in age group C) showed no essential difference clinically or at rest haemodynamically from the other patients of the series either preoperatively or at the follow-up examination about 18 months after the operation. The results for this group have been compared with values for young normal persons given by Holmgren, Jonsson and Sjöstrand (1960) and Bevegård, Holmgren and Jonsson (1960) and for older normal persons by Granath, Jonsson and Strandell (1964) and Malmborg (1964).

Of the remaining 56 patients, of whom 39 were children, exercise tests during recatheterization were either not carried out, for various reasons, or were unsatisfactory.

The results obtained on cardiac catheterization at rest and during exercise are summarized in Tables 14 and 15 and Figs 9—14. In view of the differences in haemodynamic conditions in children, women and men, the results for the different age groups are reported separately.

Circulatory function

Heart rate At rest the heart rate in the children was, on the average, 81 beats per minute, in the women in age groups B and C 72 beats per minute and in the men in age groups B and C 63 beats per minute. One girl in age group A with a heart rate of 48 had an A V block II the block being constantly 2 1 One woman with atrial fibrillation had a relatively regular slow ventricular frequency (73/min) In all other cases there was sinus rhythm with a normal frequency

Oxygen uptake At rest the oxygen uptake in the children, women and men was, on the average, 2.8 % 18.6 % and 12.4 % higher respectively than the basal oxygen uptake In the women and men the basal metabolic rate lay within the normal limits this was not investigated in the children. In no case were any clinical signs of thyroid dysfunction seen.

On cardiac catheterization during exercise the oxygen uptake increased to normal extent with increasing work loads. The mean val for the degree of mechanical efficiency was 20 % in the children and women and 22 % in the men, at a work load which increased the heart rate to an average of 134 beats/min, 134 beats/min and 123 beats/min, respectively in these three groups.

1961) In the present series only 4 patients were over 50 years of age, and there was no tendency to recurrent upper respiratory infections which may explain, at least partly the low incidence of pulmonary hypertension

No correlation was found in the present series between the size of the left-to-right shunt and the pressure gradient between the right ventricle and pulmonary artery This gradient was probably caused by the preoperatively increased flow due to the effect of "pressure loss of velocity" (Jonsson 1957)

Summary

The oxygen saturation and pressure conditions at rest before and on the average, 17 months after surgical repair of ASD sec in 107 patients are reported.

The left-to-right shunt was preoperatively on the average, 61 % of the pulmonary blood flow No significant correlation was found between the size of the left-to-right shunt expressed in % of the pulmonary blood flow and the preoperative roentgenological heart volume expressed in ml/m² body surface area, in any of the age groups. No residual shunts were found on recatheterization. The oxygen saturation in the superior vena cava was normal and significantly higher (***) postoperatively indicating preoperatively increased peripheral utilization of the oxygen content. At the follow up examination no statistically certain correlation was found between shunt reduction and reduction of the relative heart volume.

Preoperatively the pressures in the pulmonary circulation were high but within the normal range only three patients had pulmonary hypertension. On recatheterization the pressures were significantly lower in the right atrium (**) right ventricle (***) and the pulmonary artery (*) which shows that preoperatively the left-to-right shunt gave rise to a pressure increase to high normal but not pathological values. Only in the older adults, was there a significant correlation (*) between shunt size and systolic right ventricular pressure. At the follow up examination no statistically certain correlation was found between shunt reduction and reduction of systolic right ventricular pressure, in the different age groups.

The mean PCV pressure was normal and showed no significant change postoperatively and therefore the pressure gradient across the pulmonary capillary bed was essentially independent of the pulmonary blood flow On comparing the filling pressures of the ventricles pre and postoperatively it was found that before the operation, because of the defect this pressure was increased for the right ventricle and in many cases, was decreased for the left, compared with normal values. The pressure relationships and the functional mechanisms of both the right and the left ventricle were unphysiological and were prerequisite conditions for the occurrence of a left-to-right shunt, and possibly also for reduced systemic flow Postoperatively a normal pressure difference between the atria, and prerequisite conditions for normal filling pressure, were noted.

In most cases during exercise the saturation decreased to a normal extent with increasing work load and heart rate but to values which lay at the lower normal limit. Three patients in age group B showed a rather high oxygen saturation at rest, but this decreased to a normal extent during exercise. A girl in age group A with an A-V block II (2 1) showed a normal reduction of the

both at rest and during exercise. In relation to the oxygen uptake most patients showed, during exercise a somewhat high arteriovenous difference which was not quite parallel with the normal curvilinear regression line In relation to the heart rate most patients showed a normal increase of the arteriovenous oxygen difference during exercise

Cardiac output (Fig 12 A—C) At rest the mean cardiac output in age group A was 4 5 l min, with no difference between boys and girls. In the women of age group B this value was 5 7 l/min, and in those of age group C, 4.9 l/min. The corresponding values for cardiac index were 3.8, 3.5 and 3 0 l/min per m² body surface area, respectively In the men in age group B the mean cardiac output was 5.9 l/min, and in those of age group C 6.0 l/min, with corresponding cardiac index values of 3.1 and 3.0 l min per m² body surface area, respectively The cardiac index

oxygen saturation on increase of the heart rate from 48 beats/min at rest to 66 during exercise. One woman in age group C with normal resting values showed a negligible saturation reduction in relation to the heart rate. The lowest value was noted in a boy in age group A (28.6 %). During exercise no difference in the oxygen saturation in mixed venous blood was found between the different age groups.

Arteriovenous oxygen difference (Figs. 10 and 11). At *rest* the mean arteriovenous oxygen difference (AVD ml/l) was, on the average 39.2 ml/l in children, 41.2 ml/l in women and 46.5 ml/l in men. 15 patients showed values higher than 45 ml/l.

During *exercise* the values increased with increasing work loads, and varied between 71.8 and 123.0 ml/l. The arteriovenous oxygen difference values have been plotted against oxygen uptake in Fig. 10 and against heart rate in Fig. 11.

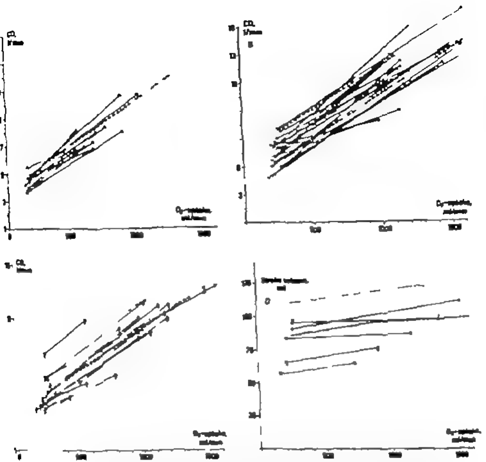

Fig. 12. Oxygen uptake (ml/min) in relation to cardiac output (l/min) at rest and during exercise. Regression lines for cardiac output on oxygen uptake in old (heavy broken line) and young (thin broken line) normal persons according to Granath et al. (1964). Symbols as in Fig. 9.

Fig. 12 A shows the conditions for 11 children in age group A,

Fig. 12 B for 18 females and 3 males in age group B, and

Fig. 12 C for 15 females and 2 males in age group C.

In Fig. 12 B and C (see arrows) there was no room for three symbols, representing cardiac output values of 14.8, 15.5 and 14.0 l/min, and oxygen uptake values of 1790, 2140 and 1720 ml/min.

Fig. 12 D. Mean stroke volume (ml) in relation to oxygen uptake (ml/min) at rest and during exercise. Mean stroke volumes in old (heavy broken line) and young (thin broken line) normal persons according to Granath et al. (1964). Squares represent children. Other symbols as in Fig. 9.

mm Hg in the women and 1.0 mm Hg in the men.

During exercise this value decreased to 4 mm Hg and –0.7 mm Hg, respectively.

These values, both at rest and during exercise, lay within the normal limits of variation.

Right ventricle. At rest the systolic pressure in the right ventricle was, on the

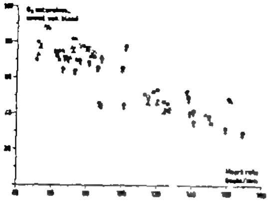

Fig 9 Oxygen saturation of mixed venous blood (in pulmonary artery) in per cent, in relation to heart rate (beats/min) at rest and during exercise. Circles represent women, triangles men open symbols = children, filled symbols = patients in age group B. Circles with crosses, and triangles with arrows represent patients in age group C.

Fig 10. Fig. 12 A shows the conditions for 11 children in age group A,

Fig. 12 B for 18 females and 5 males in age group B, and

Fig. [illegible] C for 15 females and 2 males in age group C.

In Fig. 12 B and C (see arrows) there was no room for three symbols, representing cardiac output values of 14.8, 15.5 and 14.0 l/min, and oxygen uptake values of 1790 2140 and 1720 ml/min.

Fig. 12 [illegible] Mean stroke volume (ml) in relation to oxygen uptake (ml/min) at rest and during exercise. Mean stroke volumes in old (heavy broken line) and young (thin broken line) normal persons according to Granath et al. (1964). Squares represent children. Other symbols as in Fig [illegible]

mm Hg in the women and 1.0 mm Hg in the men.

During *exercise* this value decreased to 2.4 mm Hg and −0.7 mm Hg, respectively.

These values, both at rest and during exercise, lay within the normal limits of variation.

Right ventricle. At *rest* the systolic pressure in the right ventricle was, on the

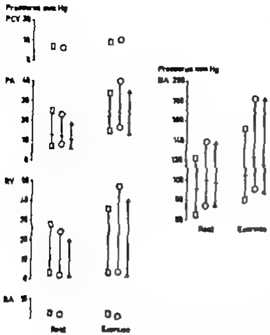

Fig 13. Mean values for pressures, in mm Hg, at rest and during exercise in 11 children (squares) 33 females (circles) and 7 males (triangles) Notation as in Table 14

average, 28 mm Hg in the children, 24 mm Hg in the women and 20 mm Hg in the men. The corresponding figures for end-diastolic pressure were 3 6, 2.3 and 2.3 mm Hg, respectively

During *exercise* these values increased with increasing work loads, to average values of 36 mm Hg in the children, 47 mm Hg in the women and 40 mm Hg in the men. The end-diastolic pressure during exercise was 3 7 mm Hg 3 8 mm Hg and 1.9 mm Hg in the three respective groups.

Pulmonary artery At *rest* the systolic pressure in the pulmonary artery was 25 mm Hg in the children 23 mm Hg in the women and 19 mm Hg in the men. At rest the systolic pressure gradient between the right ventricle and pulmonary artery was 3 mm Hg in the children and 1 mm Hg in the women and men.

During *exercise* the systolic pressure in the pulmonary artery increased in the same way as the systolic pressure in the right ventricle, and in the children this value was now 34 mm Hg in the women 40 mm Hg and in the men 35 mm Hg During exercise, the systolic pressure gradient in the children was 2 mm Hg, in the women 7 mm Hg and in the men 4 mm Hg

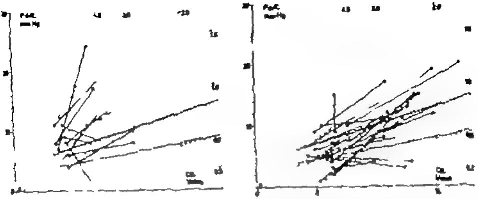
The mean pressure in the pulmonary artery at rest was 13 mm Hg in the children 13 mm Hg in the women and 11 mm Hg in the men. During exercise these values increased to 22, 24 and 19 mm Hg respectively

Pulmonary capillary venous pressure At *rest* the mean PCV pressure was 7 1 mm Hg in the children, 6.3 mm Hg in the women and 4.9 mm Hg in the men. The highest mean PCV pressure was 13 mm Hg

During *exercise* these values increased to 9 6, 10.3 and 8.7 mm Hg respectively The highest value during exercise was 18 mm Hg

Brachial artery At *rest* the systolic pressure was, on the average, 122 mm Hg in the children, 138 mm Hg in the women and 137 mm Hg in the men. The corresponding mean pressure values were 90 98 and 96 mm Hg Two women in age group C had moderate arterial hypertension with systolic pressures of 185—200 and diastolic pressures of 100 mm Hg

During *exercise* the systolic pressure increased to 152 mm Hg in the children and 182 mm Hg in the women and men. The mean pressure values for these three groups were 104 1.2 and 115 mm Hg, respectively The highest values for systol



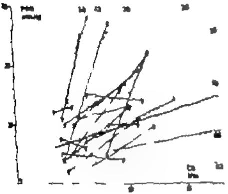


Fig. 14. Relationship between pressure gradient (Pdiff) across the pulmonary vascular bed, in mm Hg, and cardiac output (CO) l/min, at rest and during exercise. Pdiff expressed as the difference in mean pressure between PA and PCV in mm Hg. Very thin broken lines represent different isoresistance lines (R). The other broken lines are regression lines for these parameters for old (heavy lines) and young (thin lines) normal persons according to Granath et al. (1964). Symbols as in Fig. 9. Fig. 14 A shows the conditions in age group A, Fig. 14 B in age group B and Fig. 14 C in age group C.

le pressure during exercise, i.e. 240 and 270 mm Hg, were recorded in the two women who had shown raised pressure at rest.

Pulmonary vascular resistance (R_p, Fig. 14). At rest the pulmonary vascular resistance, expressed as mm Hg per l/min, was on the average, 1.6 in the children, 1.3 in the women and 1.0 in the men. The corresponding values for pulmonary vascular resistance index (R_{I_p}) expressed as mm Hg per l/min × m² body surface area were 1.8, 1.9 and 1.5 respectively. These mean values were within the normal limits, but in the older women, in particular, a tendency to an increased pulmonary vascular resistance was seen.

During *exercise* the pulmonary vascular resistance decreased in approximately one half of the patients, but large individual variations were noted in the different age groups. Compared with the resistance at rest, no statistically significant change was noted during exercise.

Systemic vascular resistance (R_s). At rest, the systemic vascular resistance, expressed as mm Hg per l/min, was, on the average, 19.6 in children, 18.1 in women and 16.9 in men. The corresponding values for systemic vascular resistance index (R_{I_s}) expressed as mm

Hg per l/min × m^2 body surface area were 23.4 26.8 and 29.2 respectively These values lay within the normal limits except in the two patients with arterial hypertension.

During *exercise* the systemic vascular resistance decreased to an essentially normal extent.

Discussion

Up to the present time no reports appear to have been made which have illustrated the haemodynamic conditions both at rest and during work in patients with surgically repaired secundum defects. It seemed of interest therefore, to study these conditions in a series of patients 18 months, on the average, after open repair of a haemodynamically uncomplicated secundum defect, where both the operation and the postoperative course were free of complications.

From a clinical aspect it is important to know not only that the defect is closed but, above all, the general cardiac condition of the patient after the operation. It was therefore of especial interest to determine whether and if so in what way this series of patients with surgically repaired secundum defects differed haemodynamically from normal subjects.

Circulatory efficiency i.e cardiac output in relation to oxygen uptake and heart rate During exercise, the majority of patients showed a somewhat higher arteriovenous oxygen difference than the normal in relation to the oxygen uptake, while, on the other hand the arteriovenous oxygen difference in relation to the heart rate was essentially normal. Since the oxygen uptake and mechanical efficiency were normal, these patients showed on the average, a lower cardiac output during exercise, but this increased, however in a normal way with increasing work loads.

The cardiac output values at rest in the different age groups lay at the lower normal limit, while the cardiac index values were within the normal range of variations. The stroke volume was, on the average, lower than the values reported for young healthy persons, and was in closer agreement with the conditions seen in older healthy men. During exercise, however the stroke volume increased to a normal extent, following in the main the values given for normal persons.

Patients with a low cardiac output in relation to the oxygen uptake, and a high arteriovenous oxygen difference in relation to the heart rate are designated as having a hypokinetic circulation, in contrast to those with a hyperkinetic circulation as pointed out e.g by Holmgren et al. (1957) A tendency to hypokinetic circulation has been demonstrated in elderly normal men, by Strandell (1964) and in asthmatic patients by Irnell (1964) In both of these series an increase in the arteriovenous oxygen *difference in relation to the oxygen uptake*, and also a reduction of the maximal heart rate, were observed with advancing age, and this resulted in a tendency to an increase in the arteriovenous difference in relation to the heart rate.

The results of the haemodynamic studies in patients with surgically repaired secundum defects were *in* close agree-

ment with the conditions in hypokinetic circulation. On the other hand, in most cases the arteriovenous difference was normal in relation to the heart rate, and therefore from this point of view these patients could be said to have a normokinetic circulation.

On making comparisons with the normal values given, consideration should be taken, not only of age, but also of the fact that these normal values are based on investigations in men, while the present series is comprised predominantly of women, in whom the circulatory efficiency may be different.

The pressures at rest in the pulmonary circulation and PCV were normal, and on the average somewhat higher in the children than in the women and men. The pressure in the brachial artery was normal in the children and adults.

During exercise the pressures increased to an essentially normal extent. The pressure increases were somewhat more pronounced in the older patients compared with the children the pressure difference between the young and older patients during exercise was in agreement with the findings of Granath et al. (1964) and may be explained by age-dependent structural changes with increasing vascular rigidity. In these patients, who before the operation, because of the left-to-right shunt, showed greatly augmented pulmonary blood flow the elasticity function in the main branch of the pulmonary artery may have been reduced. Such vascular changes are probably more pronounced in older than in young patients, and may then produce a tendency to reduced pressure tolerance, especially during exercise. The mean PCV pressure increased to a normal extent during work, this increase being somewhat higher in older than in young patients. This was in accordance with previous findings, and was probably due to the fact that the filling pressure in the left ventricle increases to some extent during exercise with advancing age (Granath et al. 1964).

The mean values for pulmonary vascular resistance were within the normal limits both at rest and during exercise, but there was a tendency to high normal or raised values among the older patients. This is explained by the fact that in these patients the pressure gradient across the pulmonary vascular bed was high, while, on the other hand, the pulmonary blood flow was low.

With a few isolated exceptions, the pressures in the brachial artery were normal both at rest and during exercise. The systemic vascular resistance was also normal both at rest and during exercise.

Summary

The haemodynamic findings at rest and during exercise are reported for 51 patients catheterized approximately 18 months after surgical repair of haemodynamically uncomplicated ASD sec. The pre- and postoperative values at rest in these patients showed no deviation from the results discussed previously for the entire series.

It was of especial interest to study the circulatory efficiency i.e. the cardiac output in relation to the oxygen uptake and heart rate. The results appeared to agree with the conditions in hypokinetic

Hg per l/min × m² body surface area, were 23.4, 26.8 and 29.2 respectively. These values lay within the normal limits except in the two patients with arterial hypertension.

During exercise the systemic vascular resistance decreased to an essentially normal extent.

Discussion

Up to the present time no reports appear to have been made which have illustrated the haemodynamic conditions both at rest and during work in patients with surgically repaired secundum defects. It seemed of interest, therefore, to study these conditions in a series of patients 18 months, on the average, after open repair of a haemodynamically uncomplicated secundum defect, where both the operation and the postoperative course were free of complications.

From a clinical aspect it is important to know not only that the defect is closed but above all the general cardiac condition of the patient after the operation. It was therefore of especial interest to determine whether and if so in what way this series of patients with surgically repaired secundum defects differed haemodynamically from normal subjects.

Circulatory efficiency, i.e. cardiac output in relation to oxygen uptake and heart rate. During exercise, the majority of patients showed a somewhat higher arteriovenous oxygen difference than the normal in relation to the oxygen uptake, while, on the other hand, the arteriovenous oxygen difference in relation to the heart rate was essentially normal. Since the oxygen uptake and mechanical efficiency were normal, these patients showed, on the average, a lower cardiac output during exercise, but this increased however in a normal way with increasing work loads.

The cardiac output values at rest in the different age groups lay at the lower normal limit, while the cardiac index values were within the normal range of variations. The stroke volume was, on the average, lower than the values reported for young healthy persons, and was in closer agreement with the conditions seen in older healthy men. During exercise, however, the stroke volume increased to a normal extent, following in the main the values given for normal persons.

Patients with a low cardiac output in relation to the oxygen uptake, and a high arteriovenous oxygen difference in relation to the heart rate, are designated as having a hypokinetic circulation, in contrast to those with a hyperkinetic circulation as pointed out e.g. by Holmgren et al. (1957). A tendency to hypokinetic circulation has been demonstrated in elderly normal men, by Strandell (1964), and in asthmatic patients by Irnell (1964). In both of these series an increase in the arteriovenous oxygen difference in relation to the oxygen uptake, and also a reduction of the maximal heart rate, were observed with advancing age, and this resulted in a tendency to an increase in the arteriovenous difference in relation to the heart rate.

The results of the haemodynamic studies in patients with surgically repaired secundum defects were in close agree

CHAPTER IX

Haemodynamic findings at rest and during exercise before and after operation in 18 patients

In 18 patients the pressure and flow determinations during exercise were carried out with the same work load before as after operation, and therefore in this series individual comparisons of certain haemodynamic functions could be made. These results are therefore reported separately.

In this small series no consideration has been taken of the sex differences in the young and older adults. In age group A there were 6 children (3 boys and 3 girls). In age group B, the young adults, there were 5 women and 2 men, and in age group C, the older adults, 4 women and 1 man. These patients were examined 11 months, on the average, after operation. The results from these investigations are summarized in Tables 16 and 17 and Figs. 15—23.

Circulatory function

Heart rate. The heart rate was essentially the same at the follow-up examination as before operation. In the children an average value of 87 beats per minute was noted preoperatively and 84 at the follow-up examination, and in the adults 74 and 67 beats per minute, respectively. In all patients sinus rhythm with a normal frequency was noted.

Oxygen uptake (Fig. 15). The oxygen uptake at rest was the same on recatheterization as preoperatively in all age groups.

During *exercise* this value rose to a normal extent with increasing work loads in the different age groups, the increase being approximately the same preoperatively *as on recatheterization.* The relationship between heart rate and oxygen uptake was also the same on both these occasions. The mean value for the mechanical efficiency was 18 % in the children, 22 % in the young adults and 21 % in the older adults, at a work load which increased the heart rate both pre- and postoperatively to 144 beats/min on the average in the children and 128 beats/min and 111 beats/min in the other two groups, respectively.

Arterial oxygen saturation. The arterial oxygen saturation, at *rest* and during *exercise* lay within the normal limits both preoperatively and on recatheterization. At rest, the mean arterial oxygen saturation in the entire series was 97.9 %, and during exercise 96.5 % with no difference between the age groups.

Oxygen saturation in superior vena cava (Fig. 16 A). At *rest* the mean oxygen saturation of blood drawn from the superior vena cava was, on the average, 71.3 % preoperatively and this remained unchanged (70.1 %) on recatheterization, in the children and young adults. In the older adults of age group C this value *was also* the same

circulation since the majority of patients, especially the children and older adults showed a cardiac output which, at rest, was low though within the normal range, but which increased in a normal way during exercise.

The pressures in the pulmonary circulation were normal at rest, and were, on the average, somewhat higher in children than in adults.

The pressure reaction during exercise was in agreement with previous findings (Granath et al. 1964) this reaction was more pronounced in the older than in the young patients, possibly due to age-dependent structural changes with increasing vascular rigidity and reduced elasticity in the pulmonary artery

The mean PCV pressure was normal both at rest and during exercise the pressure increase during exercise was somewhat more pronounced in the older than in the young patients.

The normal, or somewhat high, pressure gradient across the pulmonary capillary bed with, in many cases, a rather low pulmonary blood flow gave rise to a somewhat high pulmonary vascular resistance both at rest and during exercise, especially in the older patients.

CHAPTER IX

Haemodynamic findings at rest and during exercise before and after operation in 18 patients

In 18 patients the pressure and flow determinations during exercise were carried out with the same work load before as after operation, and therefore in this series individual comparisons of certain haemodynamic functions could be made. These results are therefore reported separately

In this small series no consideration has been taken of the sex differences in the young and older adults. In age group A there were 6 children (3 boys and 3 girls) In age group B, the young adults, there were 5 women and 2 men, and in age group C, the older adults, 4 women and 1 man. These patients were examined 11 months, on the average, after operation. The results from these investigations are summarized in Tables 16 and 17 and Figs. 15—23.

Circulatory function

Heart rate The heart rate was essentially the same at the follow-up examination as before operation. In the children an average value of 87 beats per minute was noted preoperatively and 84 at the follow-up examination, and in the adults 74 and 67 beats per minute, respectively In all patients sinus rhythm with a normal frequency was noted.

Oxygen uptake (Fig 15) The oxygen uptake at *rest* was the same on recatheterization as preoperatively in all age groups.

During *exercise* this value rose to a normal extent with increasing work loads in the different age groups, the increase being approximately the same preoperatively as on recatheterization. The relationship between heart rate and oxygen uptake was also the same on both these occasions. The mean value for the mechanical efficiency was 18 % in the children, 22 % in the young adults and 21 % in the older adults, at a work load which increased the heart rate both pre- and postoperatively to 144 beats/min on the average in the children and 128 beats/min and 111 beats/min in the other two groups, respectively

Arterial oxygen saturation. The arterial oxygen saturation, at *rest* and during *exercise* lay within the normal limits both preoperatively and on recatheterization. At rest, the mean arterial oxygen saturation in the entire series was *97.9 %* and during exercise 96.5 % with no difference between the age groups.

Oxygen saturation in superior vena cava (Fig 16 A) At *rest* the mean oxygen saturation of blood drawn from the superior vena cava was, on the average, 71.3 % preoperatively and this remained unchanged (70.1 %) on recatheterization, in the children and young adults. In the older adults of age group C this value was also the same

$$D_{I_{RV}} = \frac{RV_{SV}}{RV_D}$$

$$D_{I_{LV}} = \frac{LV_{SV}}{LV_D}$$

on both occasions, but somewhat lower viz. 65 4 %

During *exercise* the values decreased in the children and young adults to averages of 63 0 % preoperatively and 55.5 % on recatheterization. In the older adults the corresponding values were 63 1 % and 64.9 % respectively

Oxygen saturation in pulmonary artery (Fig 16 B) At *rest* the mean oxygen saturation in blood drawn from the pulmonary artery was, in the whole series, 88 8 % preoperatively and 72.0 % on recatheterization, with no difference between the age groups.

During *exercise* this value decreased in the whole series to 73 3 % on the average, preoperatively and 47 7 % on recatheterization.

Arteriovenous oxygen difference At *rest* the mean arteriovenous oxygen difference in the whole series was 17 8 ml/l preoperatively with no difference between the age groups. On recatheterization this value was somewhat greater in the older adults (49.5 ml/l) than in the children and young adults (39 9 ml/l)

During *exercise* the arteriovenous oxygen difference increased preoperatively in the whole series to an average of 46 6 ml/l. On recatheterization the value was found to have increased to 83.5 ml/l in the children and to 93 0 ml/l in the adults. In relation to the oxygen uptake most of the older patients showed on recatheterization, during exercise, a rather high arteriovenous oxygen difference, but in relation to the heart rate this increase was essentially normal.

Cardiac output (Fig 17) At *rest* the mean cardiac output in the pulmonary

values were 8.7, 8.4 and 8.7 l/min per m² body surface area, respectively.

The mean cardiac output in the systemic circulation was 5.5 l/min in the children, 5.2 l/min in the young adults and 4.0 l/min in the older adults, corresponding to cardiac index values of 2.9, 3.0 and 2.2 l/min per m² body sur-

on both occasions, but somewhat lower viz. 65 4 %

During *exercise* the values decreased in the children and young adults to averages of 63 0 % preoperatively and 55.5 % on recatheterization. In the older adults the corresponding values were 63 1 % and 64.9 % respectively

Oxygen saturation in pulmonary artery (Fig 16 B) At *rest* the mean oxygen saturation in blood drawn from the pulmonary artery was, in the whole series, 88 8 % preoperatively and 72.0 % on recatheterization with no difference between the age groups.

During *exercise* this value decreased in the whole series to 73.3 % on the average, preoperatively and 47 7 % on recatheterization.

Arteriovenous oxygen difference At *rest* the mean arteriovenous oxygen difference in the whole series was 17 8 ml/l preoperatively with no difference between the age groups. On recatheterization this value was somewhat greater in the older adults (49.5 ml/l) than in the children and young adults (39 9 ml/l)

During *exercise* the arteriovenous oxygen difference increased preoperatively in the whole series to an average of 46.6 ml/l. On recatheterization the value was found to have increased to 83.5 ml/l in the children and to 93.0 ml/l in the adults. In relation to the oxygen uptake most of the older patients showed on recatheterization, during exercise, a rather high arteriovenous oxygen difference, but in relation to the heart rate this increase was essentially normal.

Cardiac output (Fig 17) At *rest* the mean cardiac output in the pulmonary circulation before the operation was 10.2 l/min in the children, 14 0 l/min in the young adults and 15 0 l/min in the older adults. The corresponding cardiac index

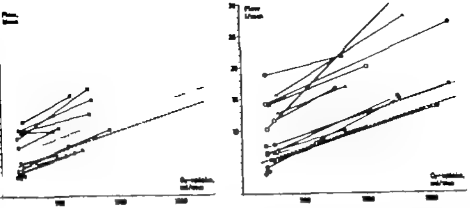

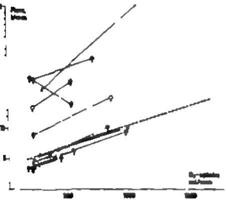

Fig. 17 Oxygen uptake (ml/min) in relation to cardiac output (l/min) in pulmonary and systemic circulation at rest and during exercise before and after operation. Regression lines between these parameters in old (heavy broken line) and young (thin broken line) normal persons according to Granath et al. (1964) Fig. 17 A shows the conditions for 6 children, Fig. 17 B for 5 women and 2 men in age group B, and Fig. 17 C for 4 women and 1 man in age group C. Squares represent children, circles women and triangles men in age group B, and circles with cross women and triangles with an arrow men in age group C. Open symbols = cardiac output in pulmonary circulation; crossed symbols = preoperative and filled symbols postoperative cardiac output in systemic circulation. In Fig. 17 B and 17 C (see arrows in figures) there was no room for two symbols, representing values for cardiac output in pulmonary circulation of 34 and 31.2 l/min and values for oxygen uptake of 1500 and 1120 ml/min, respectively

Shunt group type of defect heart volume and systolic right ventricular pressure 9 patients were in shunt group 2, and 9 in shunt group 3. 16 patients had a large central secundum defect, one child had maximal large, low defect and one patient in age group C had a sinus venosus defect with anomalous right-sided venous return to the superior vena cava. 6 patients had a normal heart volume, 9 patients showed slight cardiac enlargement, and in 3 adults there was moderate or pronounced cardiac enlargement. 11 of the 18 patients showed a systolic right ventricular pressure of 30 mm Hg or more. These haemodynamic and clinical findings were in agreement with those reported for the entire series

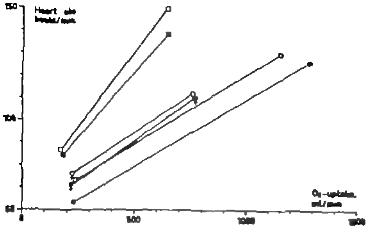

Fig 15 Mean oxygen uptake (ml/min) in relation to mean heart rate (beats/min) at rest and during exercise on catheterization before and after operation. Squares represent children, circles young adults and circles with crosses older adults. Open symbols = preoperative values, filled symbols = post operative values.

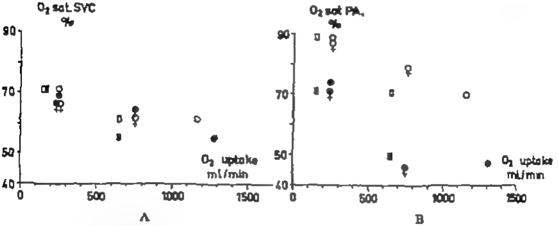

Fig 16. Mean oxygen saturation, in per cent, in relation to mean oxygen uptake, in ml/min, in superior vena cava (SVC, Fig 16 A) and pulmonary artery (PA, Fig 16 B) at rest and during exercise before and after operation. Symbols as in Fig 15

face area, respectively On recatheterization these values were 3 6, 3 6 and 2 6 respectively

During *exercise* the cardiac output in the pulmonary circulation increased by an average of 3 7 l/min in the children, 9 4 l/min in the young adults and 4.9 l/min in the older adults. These increases were normal and were of at least the same order of magnitude as the increases in cardiac output in the systemic circulation noted on recatheterization, except in one patient in age group C who had pulmonary hypertension and showed a reduced cardiac output in the pulmonary circulation preoperatively

The left-to-right shunt at rest was 6.9 l/min in the children, 8.9 l/min in the young adults and 11 0 l/min in the older adults. The corresponding values for shunt index were 5.2, 5 4 and 6.3 l/min per m^2 body surface area, respectively When expressed as per cent of the pulmonary blood flow the shunt was 67 % in the children, 65 % in the young adults and 73 % in the older adults.

In no case was a residual shunt noted on recatheterization.

to 2.0 mm Hg preoperatively and to 1.1 mm Hg on recatheterization.

Right ventricle. At *rest*, the systolic right ventricular pressure in the whole series was 30 mm Hg preoperatively and 24 mm Hg, i.e. significantly lower ( ) on recatheterization. The end-diastolic pressures were 4.4 mm Hg and 2.5 mm Hg, respectively.

During *exercise* the systolic pressure increased both preoperatively and on recatheterization, to averages of 46 mm Hg and 36 mm Hg, respectively in the children, and to 47 mm Hg and 46 mm Hg in the adults. The end-diastolic pressures were 3.7 mm Hg and 3.2 mm Hg, respectively.

Pulmonary artery. At *rest* the systolic pressure in the whole series was, on the average, 24 mm Hg preoperatively and 22 mm Hg on recatheterization. The *diastolic and mean pressures were also* normal, the mean pressures being 15 mm Hg and 13 mm Hg, respectively. The systolic pressure gradient between the right ventricle and pulmonary artery was, at rest 5 mm Hg preoperatively and 2 mm Hg on recatheterization. *One* patient had pulmonary hypertension with a systolic PA pressure of 87 mm Hg.

During *exercise* the systolic pressure in the pulmonary artery increased preoperatively to an a erage of 38 mm Hg in children nd young dults and to 52 mm Hg in older adults. The corresponding mean pressure values were now 23 mm Hg and 32 mm Hg, respectively. On recatheterization the systolic pressures were found to have increased to 37 mm Hg and the mean pressure to 23 mm Hg, in the whole series, with essentially no difference between the age groups.

Pulmonary capillary venous pressure. At *rest* the mean PCV pressure preoperatively was 5.9 mm Hg in the children and young adults and 3.7 mm Hg in the older adults. The corresponding values noted on recatheterization were 7.6 and 3.8 mm Hg, respectively.

During *exercise* the mean PCV pressure increased preoperatively to 7.5 mm Hg in the children and to 10.3 mm Hg in the adults, while the corresponding values obtained on recatheterization were 8.7 and 10.4 mm Hg, respectively.

Brachial artery. At *rest* the systolic pressure in the brachial artery preoperatively was, on the average, 119 mm Hg in the children and 130 mm Hg in the adults, while the mean pressures were 90 mm Hg and 97 mm Hg, respectively. *On recatheterization* no change was noted at rest in these pressures.

During *exercise* the systolic pressures increased to *similar extents* preoperatively and at recatheterization, i.e. to 147 mm Hg in the children and to 170 mm Hg in the adults the corresponding values for the mean pressures being 99 mm Hg and 114 mm Hg, respectively.

Left atrium. The mean pressure in the left atrium was recorded in 14 cases, and was found to be 5.2 mm Hg in the children and young adults, and 2.7 mm Hg in the older adults. The difference in mean pressure between right and left atrium was 1.8 mm Hg in the children and young adults and 0.7 mm Hg in the older adults. The difference between mean PCV pressure and mean pressure in the left atrium was, on the average, 0.8 mm Hg. The preoperative difference

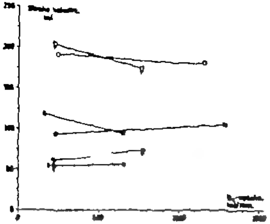

Fig. 18. Mean stroke volume (ml) in relation to mean oxygen uptake (ml/min) at rest and during exercise before and after operation. Crossed symbols = preoperative values for left ventricular stroke volume at rest. Other symbols as in Fig. 15.

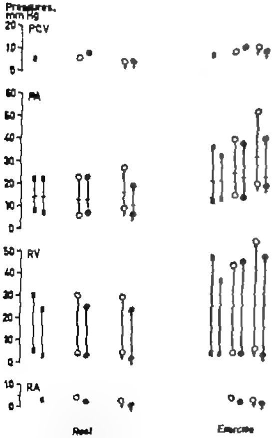

Fig 19 Mean values for pressures at rest and during exercise before and after operation. Notation as in Table 14 and symbols as in Fig 15

of 107 patients. In the small series there was no significant correlation either between the preoperative values of shunt index and heart volume or between their postoperative reductions.

Stroke volume (Fig 18) At *rest* the mean right ventricular stroke volume before operation was 119 ml in the children, 191 in the young adults and 204 ml in the older adults. The corresponding values for the left ventricle were 39, 68 and 55 ml, respectively on recatheterization these values at rest were found to have increased significantly (*) *in the children and young adults (to* 5J ml and 94 ml, respectively) but to have remained essentially unchanged (61 ml) in the older adults.

During *exercise* the right ventricular stroke volume decreased somewhat preoperatively in the children and older adults, but was essentially unchanged in the young adults. On recatheterization no change in the left ventricular stroke volume was observed in the children, compared with the resting value. In the young and older adults increases of 20 % and 10 % respectively of the resting values were noted.

Intracardiac and intravascular pressures

The results of the pressure measurements made preoperatively and at the follow up examination, both at rest and during exercise, are given in Fig 19

Right atrium. At rest preoperatively the mean RA pressure in the whole series was 2.9 mm Hg, and on recatheterization it was significantly (*) lower viz. 1.5 mm Hg

During *exercise* there was a reduction

to 2.0 mm Hg preoperatively and to 1.1 mm Hg on recatheterization.

Right ventricle. At *rest* the systolic right ventricular pressure in the whole series was 30 mm Hg preoperatively and 24 mm Hg, i.e. significantly lower ( ) on recatheterization. The end-diastolic pressures were 4.4 mm Hg and 2.3 mm Hg, respectively.

During *exercise* the systolic pressure increased both preoperatively and on recatheterization, to averages of 46 mm Hg and 36 mm Hg, respectively in the children, and to 47 mm Hg and 46 mm Hg in the adults. The end-diastolic pressures were 3.7 mm Hg and 3.2 mm Hg, respectively.

Pulmonary artery. At *rest* the systolic pressure in the whole series was, on the average, 24 mm Hg preoperatively and [illegible] mm Hg on recatheterization. The diastolic and mean pressures were also normal, the mean pressures being 15 mm Hg and 13 mm Hg, respectively. The systolic pressure gradient between the right ventricle and pulmonary artery was, at rest 5 mm Hg preoperatively and 8 mm Hg on recatheterization. One patient had pulmonary hypertension with a systolic PA pressure of 87 mm Hg.

During *exercise* the systolic pressure in the pulmonary artery increased preoperatively to an average of 38 mm Hg in children and young adults and to 52 mm Hg in older adults. The corresponding mean pressure values were now 23 mm Hg and 32 mm Hg, respectively. On recatheterization the systolic pressures were found to have increased to 37 mm Hg and the mean pressure to 23 mm Hg, in the whole series, with essentially no difference between the age groups.

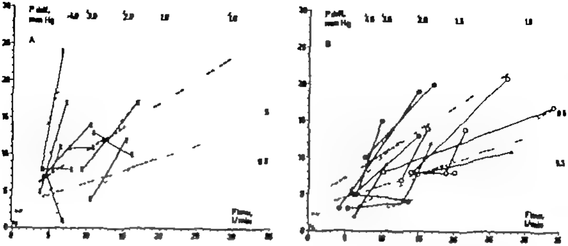
Pulmonary capillary venous pressure. At *rest* the mean PCV pressure preoperatively was 5.9 mm Hg in the children and young adults and 3.7 mm Hg in the older adults. The corresponding values noted on recatheterization were 7.6 and 3.8 mm Hg, respectively.

During *exercise* the mean PCV pressure increased preoperatively to 7.5 mm Hg in the children and to 10.3 mm Hg in the adults, while the corresponding values obtained on recatheterization were 8.7 and 10.4 mm Hg, respectively.

Brachial artery. At *rest* the systolic pressure in the brachial artery preoperatively was, on the average, 119 mm Hg in the children and 130 mm Hg in the adults, while the mean pressures were 90 mm Hg and 92 mm Hg, respectively. On recatheterization no change was noted at rest in these pressures.

During *exercise* the systolic pressures increased to similar extents preoperatively and at recatheterization, i.e. to 147 mm Hg in the children and to 170 mm Hg in the adults, the corresponding values for the mean pressures being 99 mm Hg and 114 mm Hg, respectively.

Left atrium. The mean pressure in the left atrium was recorded in 14 cases, and was found to be 3.2 mm Hg in the children and young adults, and 2.7 mm Hg in the older adults. The difference in mean pressure between right and left atrium was 1.8 mm Hg in the children and young adults and 0.7 mm Hg in the older adults. The difference between mean PCV pressure and mean pressure in the left atrium was, on the average, 0.8 mm Hg. The preoperative difference



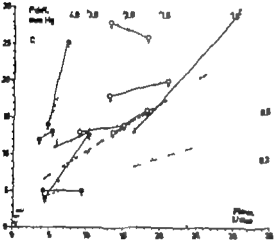


Fig 20 Relationship between pressure gradient (Pdiff) across the pulmonary vascular bed, in mm Hg, and cardiac *output* (CO) *l/min*, at rest and during exercise before and after operation. *Pdiff expressed as the difference in* mean pressure between PA and PCV in mm Hg Very thin broken lines represent different isoresistance lines (R) The other broken lines are regression lines for these parameters for old (heavy lines) and young (thin lines) normal persons according to Granath et al. (1964) Symbols as in Fig 17

Fig 20 A shows the conditions in age group A for 2 children there was no resistance determination during exercise preoperatively Fig. 20 B shows the conditions in age group B, and Fig 20 C in age group C.

in mean pressure between PCV and right atrium was 2.5 mm Hg for the children and young adults and 1 7 *mm Hg for* the older adults. On recatheterization these values were found *to be 5 1* mm Hg and 4.2 mm Hg

Left ventricle The systolic pressure in the left ventricle was 104 mm Hg in the children and young adults and 127 mm Hg in the older adults. The end-diastolic pressures were 7 4 mm Hg and 3 7 mm Hg, *respectively*

Pulmonary vascular resistance (Fig 20) At *rest* the pulmonary vascular resistance was 0 8 in the children, 0 5 in the young adults and 1.2 in the older *adults, preoperatively and 1 6 0.9* and 1 8, respectively on recatheterization. There was thus an average increase in all three groups in the children (**) and young adults (*) this was statistically significant but not in the older adults.

During *exercise* no statistically certain *change* in the pulmonary resistance was noted either preoperatively or at recatheterization, compared with the respective resting values. In one half of the patients a decrease in pulmonary vascular resist

ance was seen, but there were large individual variations.

Systemic vascular resistance. At rest, preoperatively the systemic vascular resistance was 26.5 in the children, 19.4 in the young adults and 22.9 in the older adults, and on recatheterization 18.5, 15.4 and 19.5 respectively. This meant a significantly reduced value in the children (**) but no significant change in the adults.

Ventricular work index (Fig. 21). The ventricular work index (see equation in Table 16) was calculated according to Dexter (1951). For the right ventricular work index a significant (***) reduction was noted on recatheterization, both at rest and during exercise, compared with the preoperative values. The left ventricular work index was significantly ( ) higher postoperatively at rest. Preoperatively the right ventricular work index was somewhat higher in the older than in the young patients, both at rest and during exercise.

Ventricular distensibility index (Fig. 22). The ventricular distensibility index (see equation in Table 16) was calculated according to Rowe et al. (1961) and for the right ventricle this was significantly (**) lower postoperatively than preoperatively both at rest and during exercise.

The distensibility index for the left ventricle was assessed with the reservation that for the postoperative value an approximate value for the left ventricular end-diastolic pressure, calculated from PCV had to be used. The left ventricular distensibility index, at rest, was the same postoperatively as preoperatively and was significantly (***)

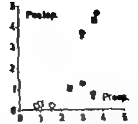

Fig. 21. Ventricular work index at rest and during exercise before and after operation.

Symbols: Squares = children, circles = young adults and circles with cross = older adults. Open symbols = right ventricular work index at rest. Filled symbols = right ventricular work index during exercise. Crossed symbols = left ventricular work index at rest.

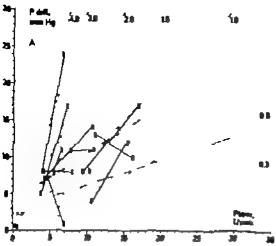
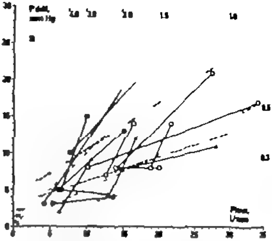
lower than the right ventricular distensibility index.

Discussion

The predominant haemodynamic finding in uncomplicated atrial septal defect of the secundum type is the left-to-right shunt, where a volume corresponding to the size of the shunt is ineffective both





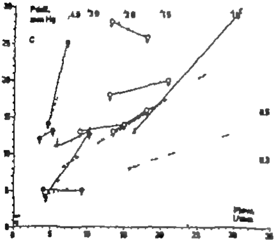


Fig 20 Relationship between pressure gradient (Pdiff) across the pulmonary vascular bed, in mm Hg, and cardiac output (CO) l/min, at rest and during exercise before and after operation. Pdiff expressed as the difference in mean pressure between PA and PCV in mm Hg Very thin broken lines represent different isoresistance lines (R) The other broken lines are regression lines for these parameters for old (heavy lines) and young (thin lines) normal persons according to Granath et al. (1964) Symbols as in Fig 17

Fig 20 A shows the conditions in age group A for 2 children there was no resistance determination during exercise preoperatively Fig. 20 B shows the conditions in age group B, and Fig 20 C in age group C.

in mean pressure between PCV and right atrium was 2.5 mm Hg for the children and young adults and 1 7 mm Hg for the older adults. On recatheterization these values were found to be 5 1 mm Hg and 4 ? mm Hg

Left ventricle The systolic pressure in the left ventricle was 104 mm Hg in the children and young adults and 127 mm Hg in the older adults. The end-diastolic pressures were 7 4 mm Hg and 3 7 mm Hg, respectively

Pulmonary vascular resistance (Fig 20) At *rest* the pulmonary vascular resistance was 0 8 in the children, 0.5 in the young adults and 1.2 in the older adults, preoperatively and 1 6, 0.9 and 1 8, respectively on recatheterization. There was thus an average increase in all three groups in the children (**) and young adults (*) this was statistically significant but not in the older adults.

During *exercise* no statistically certain change in the pulmonary resistance was noted either preoperatively or at recatheterization, compared with the respective resting values. In one half of the patients a decrease in pulmonary vascular resist

at rest was significantly lower preoperatively in the children (**) than at recatheterization, but in the adults it was only slightly lower. Preoperatively, however, in consideration of the cardiac output in the pulmonary circulation the cardiac output in the systemic circulation increased to a probably normal extent during exercise. It may thus be assumed that, in these patients, even before the operation there was a tendency to hypokinetic systemic circulation with a low left ventricular output during exercise.

In order to compare the mechanical efficiency of the ventricles before and after the operation the ventricular work index and distensibility index were calculated. At rest, both these indices showed a significant reduction for the right ventricle on recatheterization. The different haemodynamic parameters which may be related to the left-to-right shunt in atrial septal defect have long been subjected to investigation. Rowe et al. (1961) who studied such parameters at rest, found that the only significant correlation was that between the size of the left-to-right shunt and the difference in distensibility index between the right and left ventricle. In Rowe's study however 4 out of 24 patients had pronounced pulmonary hypertension of the obstructive type, in three cases combined with right-to-left shunt. In the present series there was no correlation between distensibility index and left-to-right shunt.

The shunt volume in atrial septal defect is governed predominantly by the diastolic distensibility of the right ventricle. Dexter (1956) found that the

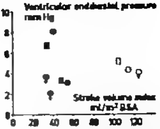

Fig. 23. Ventricular end-diastolic pressure (mm Hg) in relation to ventricular stroke volume index (ml/m body surface area). Squares = children, circles = young adults and circles with cross = older adults. Open symbols = preoperative, and filled symbols = postoperative right ventricular stroke volume index. Crossed symbols = preoperative left ventricular stroke volume index.

capacity of the right ventricle to pump large volumes with a low filling pressure differs somewhat from the conditions in the left ventricle which (according to Starling's law) requires increasing filling pressures for increasing stroke volumes. When, in the present series, the end-diastolic pressure of the right ventricle is plotted against the stroke volume index of the right ventricle, the output of the right ventricle preoperatively is found to be large in relation to the end-diastolic pressure of the right ventricle, which lies at a normal level (Fig. 23). The preoperative end-diastolic pressure in the right ventricle was significantly higher (*) than at the follow-up examination, as also was the mean pressure in the right atrium. These pressures were probably sufficiently high to permit, in view of the distensibility and function curves of the ventricles, a large increase in filling of the right ventricle. The distensibility is determined mainly by the ventricular

as regards oxygen transport and muscular work capacity The left to-right shunt involves, in particular increased work for the right ventricle, while, on the other hand, the work of the left ventricle is unchanged or possibly somewhat reduced with a decrease in the systemic flow

During exercise the size of the left to-right shunt in atrial septal defect cannot be determined with the current methods of blood-gas analysis. An approximate estimate can be made during exercise however At rest the output of the left ventricle is normal or somewhat low while that of the right ventricle is greatly increased. During exercise the output of the right ventricle may increase to a smaller extent than normally and the stroke volume of the right ventricle decreases considerably with the result that the left to-right shunt decreases to the advantage of the left ventricular output which is augmented If the output of the right ventricle increases to a normal extent, it may be expected that the shunt will remain unchanged. If on the other hand the shunt were to increase during exercise this would result in a pronounced increase of the output of the right ventricle. If the left to-right shunt were to decrease greatly or entirely this would result in a reduction of the saturation value in the pulmonary artery to a level which with respect to work, was normal, i.e. 40—50 %

In all but two patients the flow in the pulmonary circulation increased preoperatively during exercise, the exceptions being the patient with pulmonary hypertension and a girl in age group A. Fig 17 shows that in the three age groups this increase was approximately of the same order of size as that noted on recatheterization. This indicates that during exercise the left to-right shunt in l/min in these patients was essentially unchanged, with a probably normal increase in the output of both the right and left ventricles. This is supported by the fact that the preoperative reduction of the saturation values in the pulmonary artery during exercise was very moderate compared with the result obtained on recatheterization, and also by the fact that preoperatively the right ventricular stroke volume decreased only negligibly during exercise.

Jonsson et al. (1957) found that the left to-right shunt in atrial septal defect decreased during exercise in 5 of 10 patients, but recently Davies and Gazetopoulos (1966) observed that in atrial septal defect with low pulmonary vascular resistance there were *parallel* increases in the systemic and pulmonary flow during exercise with little change in the magnitude of the left to-right shunt. This is in closer agreement to the present results, which also show this tendency on more strenuous exercise. In their series of 5 patients, Davies and Gazetopoulos had lower work loads throughout in their exercise tests, corresponding to an average oxygen consumption of 460 ml/min.

As in the larger present series of patients who underwent follow-up examination, a low cardiac output at rest, with a tendency to a hypokinetic circulation during exercise, was noted in this smaller group also In addition, the cardiac index in the systemic circulation

at rest was significantly lower preoperatively in the children (**) than at re-catheterization, but in the adults it was only slightly lower. Preoperatively however in consideration of the cardiac output in the pulmonary circulation the cardiac output in the systemic circulation increased to a probably normal extent during exercise. It may thus be assumed that, in these patients, even before the operation there was a tendency to hypokinetic systemic circulation with a low left ventricular output during exercise.

In order to compare the mechanical efficiency of the ventricles before and after the operation the ventricular work index and distensibility index were calculated. At rest, both these indices showed a significant reduction for the right ventricle on recatheterization. The different haemodynamic parameters which may be related to the left-to-right shunt in atrial septal defect have long been subjected to investigation. Rowe et al. (1961) who studied such parameters at rest, found that the only significant correlation was that between the size of the left-to-right shunt and the difference in distensibility index between the right and left ventricle. In Rowe's study however 4 out of 24 patients had pronounced pulmonary hypertension of the obstructive type, in three cases combined with a right-to-left shunt. In the present series there was no correlation between distensibility index and left-to-right shunt.

The shunt volume in atrial septal defect is governed predominantly by the diastolic distensibility of the right ventricle. Dexter (1956) found that the

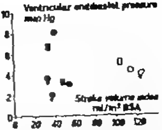

Fig. 23. Ventricular end-diastolic pressure (mm Hg) in relation to ventricular stroke volume index (ml/m² body surface area). Squares = children, circles = young adults and circles with cross = older adults. Open symbols = preoperative, and filled symbols = postoperative right ventricular stroke volume index. Crossed symbols = preoperative left ventricular stroke volume index.

capacity of the right ventricle to pump large volumes with a low filling pressure differs somewhat from the conditions in the left ventricle which (according to Starling's law) requires increasing filling pressures for increasing stroke volumes. When, in the present series, the end-diastolic pressure of the right ventricle is plotted against the stroke volume index of the right ventricle, the output of the right ventricle preoperatively is found to be large in relation to the end-diastolic pressure of the right ventricle, which lies at a normal level (Fig. 23). The preoperative end-diastolic pressure in the right ventricle was significantly higher (*) than at the follow-up examination, as also was the mean pressure in the right atrium. These pressures were probably sufficiently high to permit, in view of the distensibility and function curves of the ventricles, a large increase in filling of the right ventricle. The distensibility is determined mainly by the ventricular

wall thickness, which in turn is influenced by the systolic ventricular pressure and stroke volume. But like the mean pressure in the atrium, for technical reasons the end-diastolic ventricular pressure is also often difficult to determine and compare. Obviously this limits the value of the distensibility index in the present calculations. With this reservation the distensibility index for the right ventricle was determined in the present series, however and was found to be 25 on the average, preoperatively and 17 i.e. significantly lower (**) at the follow-up examination.

Depending on the degree and type of outflow obstruction in the right ventricle, the end-diastolic right ventricular pressure varies more than the pressure difference across the pulmonary vascular bed. Relatively accurate values can be obtained for the distensibility index for the left ventricle preoperatively whereas postoperatively the estimated values are only very approximate.

It seemed therefore more adequate to calculate the mechanical efficiency on the basis of the ventricular work index, which also can be determined more accurately during exercise. Postoperatively the right ventricular work index was significantly (***) lower and the left significantly (*) higher than preoperatively This may be an indication of satisfactory restitution of the ventricular function postoperatively despite the greatly increased load on the right ventricle before the operation.

In this series the pressures have also been reported with a view to comparing the pressure reaction during exercise before and after the operation. Preoperatively these pressures, with the exception of the PCV pressure, lay at the upper normal limit, and on recatheterization those in the right atrium and ventricle were significantly reduced (*) while the pulmonary arterial pressure was somewhat lower The PCV pressure remained essentially normal.

During exercise there was no significant difference between the preoperative values and those obtained on recatheterization for the pressures in the pulmonary artery The pressure reaction during exercise was normal in these patients on recatheterization and therefore the preoperative pressure reaction can also be regarded as normal in spite of the greatly augmented pulmonary blood flow at that time. A largely increased cardiac output in the pulmonary circulation at rest, with high normal pressures in the pulmonary artery and a low flow resistance across the pulmonary vascular bed thus allowed normal circulatory adaptation during exercise.

The pulmonary vascular resistance was somewhat higher throughout in the older than in the young patients both preoperatively and at the follow up examination, at rest and during exercise.

At recatheterization the pulmonary vascular resistance at rest was significantly higher in the children (**) and young adults (*) than preoperatively which is explained by the fact that after the operation the pressure reduction over the pulmonary vascular bed was usually considerably less pronounced than the decrease in the pulmonary blood flow In the older adults the pulmonary vascular resistance was found on recatheterization to be slightly higher but still at the

upper normal level, and in these patients the *postoperative* pressure reduction in the pulmonary artery was, on the average, somewhat more pronounced than in the children and young adults.

During exercise, however an abnormal reaction was noted in half of the patients, with increased pulmonary vascular resistance, but no relationship was found between this reaction and either the physical work capacity preoperative shunt or heart size.

The pressures in the brachial artery were normal both at rest and during exercise, with no difference between the preoperative values and those obtained on recatheterization. The systemic vascular resistance showed some reduction on recatheterization, but the values remained within the normal limits.

Summary

The results from haemodynamic investigations at rest and during exercise in 18 patients before and 11 months, on the average, after surgical repair of ASD sec are reported. One patient had pulmonary hypertension before the operation, but the values for the remaining patients did not deviate essentially from those reported for the whole series. Since the exercise tests were performed with the same work loads before as after operation, individual comparisons of the haemodynamic results could be made.

The heart rate and oxygen uptake were the same postoperatively as preoperatively both at rest and during exercise. An approximate evaluation of the magnitude of the left-to-right shunt during exercise was made by comparison between the pre- and postoperative flow conditions in the systemic and pulmonary circulations the shunt appeared to remain unchanged by exercise. A tendency to hypokinetic circulation was observed postoperatively and this was probably more pronounced before the operation.

The distensibility index for the right ventricle was significantly higher (**) preoperatively than postoperatively both at rest and during exercise at rest, this index was *significantly* higher (***) for the right than for the left ventricle, both pre and postoperatively.

A more accurate indication of the mechanical efficiency of the ventricles was the work index. This was significantly lower (***) postoperatively for the right ventricle, and this indicated satisfactory restitution of the ventricular function despite the preoperatively greatly increased work load for the ventricle.

The pressures at rest, pre- and postoperatively agreed with previously reported values for normal persons. The pulmonary vascular resistance values lay on the average, within the normal limits both at rest and during exercise, but preoperatively they were usually low and postoperatively somewhat higher. During exercise, however an abnormal increase of the pulmonary vascular resistance was noted in half of the patients. There was no relationship, however between this reaction and *either physical* work capacity preoperative shunt or heart size.

There was no statistically significant correlation either between the preoperative values of shunt index and heart volume or between their postoperative reductions.

wall thickness, which in turn is influenced by the systolic ventricular pressure and stroke volume. But, like the mean pressure in the atrium, for technical reasons the end-diastolic ventricular pressure is also often difficult to determine and compare. Obviously this limits the value of the distensibility index in the present calculations. With this reservation the distensibility index for the right ventricle was determined in the present series, however and was found to be 25 on the average, preoperatively and 17, i.e. significantly lower (**) at the follow up examination.

Depending on the degree and type of outflow obstruction in the right ventricle, the end-diastolic right ventricular pressure varies more than the pressure difference across the pulmonary vascular bed. Relatively accurate values can be obtained for the distensibility index for the left ventricle preoperatively whereas postoperatively the estimated values are only very approximate.

It seemed therefore more adequate to calculate the mechanical efficiency on the basis of the ventricular work index, which also can be determined more accurately during exercise. Postoperatively the right ventricular work index was significantly (***) lower and the left significantly (*) higher than preoperatively. This may be an indication of satisfactory restitution of the ventricular function postoperatively despite the greatly increased load on the right ventricle before the operation.

In this series the pressures have also been reported with a view to comparing the pressure reaction during exercise before and after the operation. Preoperatively these pressures, with the exception of the PCV pressure, lay at the upper normal limit, and on recatheterization those in the right atrium and ventricle were significantly reduced (*) while the pulmonary arterial pressure was somewhat lower The PCV pressure remained essentially normal.

During exercise there was no significant difference between the preoperative values and those obtained on recatheterization for the pressures in the pulmonary artery The pressure reaction during exercise was normal in these patients on recatheterization and therefore the preoperative pressure reaction can also be regarded as normal in spite of the greatly augmented pulmonary blood flow at that time. A largely increased cardiac output in the pulmonary circulation at rest, with high normal pressures in the pulmonary artery and a low flow resistance across the pulmonary vascular bed thus allowed normal circulatory adaptation during exercise.

The pulmonary vascular resistance was somewhat higher throughout in the older than in the young patients both preoperatively and at the follow-up examination, at rest and during exercise.

At recatheterization the pulmonary vascular resistance at rest was significantly higher in the children (**) and young adults (*) than preoperatively which is explained by the fact that after the operation the pressure reduction over the pulmonary vascular bed was usually considerably less pronounced than the decrease in the pulmonary blood flow In the older adults the pulmonary vascular resistance was found on recatheterization to be slightly higher but still at the

this investigation is hardly considered justifiable nowadays, since it has been found difficult to assess the position and size of the defect with certainty.

In the differential diagnosis between atrial septal defect of the secundum type (dorsal defect) and atrial septal defect of the primum type (ventral defect) the value of an angiocardiography is very limited owing, in particular, to the difficulty in determining with certainty the lower margin of the defect. Correct differentiation between these two types of defect is the deciding factor for the choice of operation method, since patients with a primum defect can only be operated on with the aid of extracorporeal circulation. The ECG pattern is the main guiding factor for this differential diagnosis (Toscano Barbosa et al. 1958, Arntzenius et al. 1963). In the present series extracorporeal circulation was used in four cases, where a primum defect could not be excluded. These patients showed the ECG pattern of the transitional, non-classic ASD sec type which can occur with a primum defect.

In spite of the perimyocardial disturbance in the postoperative stage, no signs of constrictive reaction were seen in this series at the follow-up examination, which may have been due to the fact that the pericardium was left open at the operation. The residual pathological T wave which became "normal" only during the exercise test, and was observed in 37 per cent of the cases, is difficult to assess from a prognostic aspect. In these patients, however, the myocardial metabolism during hypothermia and coronary perfusion is unknown. Up to the present, however, these T wave changes have not been found to be prognostically unfavourable, and should not give reason for an especially prolonged convalescence period for the patient in question.

The preoperatively low filling pressure in the left ventricle may explain the fact that a number of cases showed a low normal or reduced left ventricular output. These changes in the central circulation also resulted in a tendency to hypokinetic systemic circulation with reduced cardiac output in relation to oxygen uptake. Preoperatively the oxygen saturation in the superior vena cava was at a low normal level, but increased significantly (***) after the operation to a normal value. This may be an expression of a regulative mechanism with preoperatively increased peripheral utilization of the oxygen content.

In uncomplicated cases of ASD sec, closure of the defect restores the normal pressure conditions and creates the prerequisites for a normal central circulation. In spite of this, however, in a number of cases, especially children and older adults, a tendency to hypokinetic circulation was observed at the follow-up examination. In such cases controlled physical training, introduced gradually should be appropriate, and should improve the systemic circulation, and also, the psychological condition. This applies particularly to older patients, in whom a tendency to a long convalescence period probably has the directly opposite effect.

In uncomplicated cases of ASD sec the period of convalescence in adult patients should not necessarily be much longer than in children, and 6—8 weeks would seem sufficient.

General discussion and conclusions

The evaluation of the operation results in this series is based both on comparisons between preoperative and postoperative findings, where the patient serves as his own control and on comparisons of these values with known values from healthy normal subjects. In this way an idea is obtained of the *effect of the operation* The absence of a control series means, however that no opinion can be expressed with certainty as to the *prognosis without operation* since, as discussed in the introduction the variations in the natural history of the disease are wide.

In this series the indication for operation was a left to-right shunt of at least 30 % of the pulmonary blood flow With the low mortality figure and the low frequency of severe complications with the operation methods used here, it was justifiable to accept patients with small shunts also for operation.

The impression is obtained that the most suitable time for operation is at pre school or school age In this age group (age group A) both the duration of hospitalization and the convalescence period were considerably shorter than in adults. From social and psychological aspects, also, an operation is probably more easily acceptable in children, where the operation often is of a preventive nature The indication for operation in adults may on the other hand, be somewhat narrower but surgery should be advised with shunts of 50 % or more of the pulmonary blood flow

The physical cardiac findings both before and after operation were in agreement with those usually found in cases with ASD sec. In this series no relationship was found between the duration of the QRS complex and the degree of splitting of the second heart sound, either before or after operation, and therefore the residual pathologically split second sound, which was the most characteristic postoperative physical cardiac finding, can probably be explained by reduced elasticity in the pulmonary artery Preoperatively from the diagnostic point of view the splitting of the second heart sound and the diastolic filling murmur are the most important physical findings. Together with the typical ECG pattern and chest roentgenogram these findings, in most cases, form the basis for the final diagnosis in ASD sec. But the cardiological findings are not always typical and, furthermore, cannot usually provide any information about the presence or absence of anomalous venous return, so that up to now heart catheterization has been included in the clinical routine examination. In the present series the fact that the ASD sec was combined with partial anomalous pulmonary venous return in 19 per cent did not influence the choice of operation method but this is conceivable in isolated cases. In cases with partial anomalous pulmonary venous return an angiocardiography can give valuable information, while on the other hand in uncomplicated ASD sec

circulation disappears instantly after repair of an atrial septal defect. Normalization of heart sounds and murmurs, and also of the roentgenological heart volume takes place gradually. A faint systolic murmur was heard, however after the operation, probably caused by turbulent flow through the still dilated pulmonary artery. Reduced elasticity in the wall of the pulmonary artery may also explain the extensive splitting of the second heart sound after the operation while, compared with the preoperative conditions, the reduced flow volume may allow some physiological variation of the sound components.

In many cases of the present series there was some relationship between the size of the left-to-right shunt and the heart volume, but no significant correlation was found. A significant reduction was found in the roentgenological heart volume after the operation, however. On the other hand there was no statistically certain correlation between shunt reduction and reduction of heart volume.

On comparing the QRS pattern before and after operation it was found that this pattern in lead V remained unchanged, i.e. pathological, in about 50 % of the cases. Even though the *type* of QRS complex remained unchanged, however the *degree* of abnormality decreased. The amplitude reduction may correspond to regression of hypertrophy and/or dilatation in the right ventricular outflow tract. A residual pathological QRS pattern may point to a congenital abnormality in the right bundle branch, which will persist after surgery.

A pathological QRS complex in lead V_1 was not an expression of residual shunt.

At the follow-up examination a residual pathological T wave was found, and a *normalization* of this T wave during exercise was observed. The reason for this "status post myocardial lesion" reaction is discussed and is considered to be of no functional importance. This pathological T wave in the precordial leads at rest, though observed for a long period after the operation, should not be regarded as unfavourable.

Before the operation *the left-to-right* shunt in the entire series was, on the average, 61 % of the pulmonary *blood* flow.

At the *follow up examination* no residual shunts were found. The oxygen saturation in the superior vena cava lay at a normal level at the follow-up examination but was significantly higher than before the operation.

The postoperative pressure reaction in the pulmonary circulation, with reduction from preoperatively slightly raised or high normal pressure levels to normal values, was explained by the hyperkinetic *effect of the left to-right shunt*. Only in older adults was there a significant correlation between shunt size and systolic right ventricular pressure, but at the follow-up examination no correlation was found between pressure reduction and shunt.

On comparing the filling pressure of the ventricles before and after the operation it was found that, preoperatively *this* pressure was raised for the right ventricle and, in many cases, was lowered for the left. *This change* in the central circulation resulted in many cases in a low normal or reduced *left ventricular*

General summary

The main purpose of this investigation was to study the results of open heart surgery in atrial septal defects of the secundum type (ASD sec) The study was made on 107 patients, comprising a haemodynamically uncomplicated, uniform series of atrial septal defects of the secundum type, examined before and, on the average, 17 months after the operation.

Open repair was performed under hypothermia in 94 patients and with the aid of extracorporeal circulation in 13 patients. All patients were operated on by the same surgeon (V O Björk) The postoperative mortality was as low as 0.9 % and the total mortality 2.6 %

The clinical features and cardiological findings before and after operation were studied.

The ECG pattern before and after operation, the development of the ECG changes immediately after the operation and the ECG reaction during exercise tests at the follow up examination were analysed.

Haemodynamic studies were made by means of heart catheterization before the operation to estimate the significance and size of the left to-right shunt and at the follow up examination to prove that the defect was closed, but also for determination of circulatory dimensions at rest and during exercise for comparison with normal persons.

From a clinical aspect it was important to know not only that the defect was completely closed but, above all, the general cardiac condition of the patient after the operation.

The patients were divided into three age groups according to age at the time of operation, as follows A paediatric group of 50 patients below the age of 15 years, a group of 29 young adults of ages 15—29 years, and a group of 28 older adults of 30 years of age or older

The patients were also classified into function classes, and shunt and X ray groups.

The murmur was usually discovered at a routine examination during the pre-school or school period but was often rediscovered at a later examination. Only 5 out of 107 patients had sought medical advice for symptoms which could be related to cardiac disorder Preoperatively 44 patients had symptoms. The functional deterioration began after the age of 20 years.

After the operation almost all patients were symptom-free, but no significant change in the physical work capacity was found.

The physical findings before and after operation in this series were in agreement with previous findings in uncomplicated ASD sec. The excess volume load on the right heart and pulmonary

Acknowledgements

This investigation was carried out at the Paediatric Clinic, University Hospital, Uppsala, and was made possible by the cooperation and valuable assistance given by various departments and laboratories of this Hospital.

I wish to express my sincere thanks to

Professor Bo Vahlquist, Head of the Paediatric Clinic, for his valuable support and advice during the course of the investigation.

Associate professor Magnus Michaëlsson, Head of the Cardiac Laboratory at the Paediatric Clinic for his unfailing help and advice, and positive criticism.

Professor Gunnar Ström, Head of the Department of Clinical Physiology who generously placed his laboratory at my disposal and during the different phases of this study always found time for discussions on various problems involved, and who has offered much valuable and constructive criticism.

Professor Viking Olof Björk, Stockholm, former Head of the Department of Thoracic Surgery, who originally suggested this study and who has followed my work with continuous interest and encouragement.

Professor Erik Ask Upmark, Head of the Department of Internal Medicine, who has kindly given me access to his department and generously placed at my disposal all information about cases treated in his clinic.

Associate Professor Ingemar Cullhed and Dr Ebba Engholt for their valuable and cooperative assistance, and Associate Professor Lars Irnell for much helpful discussion.

Professor Folke Knutsson, Head of the Department of Diagnostic Radiology, Associate Professors Herman Lodin and Lars Björk who placed their laboratory at my disposal and gave me valuable help in evaluating the X-ray films.

I wish to thank Mr Adam Taube, lecturer in statistics for his helpful discussions and valuable assistance with the statistical problems.

My thanks are also due to members of the staffs of the Departments of Paediatrics, Clinical Physiology, Thoracic Surgery, Internal Medicine and Diagnostic Radiology, University Hospital, to Mrs Maud Marsden for translating the Swedish text and to Nurse Anita le Grand for valuable technical assistance. I also express my thanks to Miss Kerstin Sjöberg who has patiently written out the different Swedish and English copies of the manuscript and to Mrs Birgit Häggkvist for invaluable help with the figure drawings.

The work has been financially supported by grants from the Swedish National Association for Heart and Chest Diseases and from the Medical Faculty of the University of Uppsala.

output with a tendency to hypokinetic circulation. Preoperatively the oxygen saturation in the superior vena cava was at a low normal level and this may be an expression of a regulative mechanism with increased peripheral utilization of the oxygen content.

The circulatory efficiency i.e. the cardiac output in relation to oxygen uptake was analysed in a series of patients at the follow up examination. The results appeared to agree with the conditions in hypokinetic circulation. Children and older adults, especially showed low values for cardiac output both at rest and during exercise. This, in combination with a "high normal" pressure gradient across the pulmonary capillary bed gave rise to a somewhat high pulmonary vascular resistance.

In 18 patients individual comparisons of haemodynamic conditions before and after operation were made, both at rest and during exercise. An approximate evaluation of the magnitude of the left to-right shunt during exercise was made by comparison between the pre and postoperative flow conditions in the systemic and pulmonary circulation, and thus showed that the shunt appeared to remain unchanged by exercise. A tendency to hypokinetic systemic circulation was observed postoperatively and may have been more pronounced before the operation.

In uncomplicated cases of ASD sec, closure of the defect creates the prerequisites for a normal circulation. In patients with a tendency to hypokinetic circulation after the operation controlled physical training should improve the systemic circulation

Cremer [1] is generally credited with being the first to obtain esophageal leads. Since then, a number of experimental and clinical studies in adults have appeared—including those of Lieberson & Lieberson [32], Brown [9], Helm et al. [26], Deglande & Laubry [19], Nyboer [35], Myers & Klein [34], Kistin et al [28], and Scherlis et al. [40]. However even in adults, normal values are based on relatively small numbers of healthy individuals. Not until 1932 was an analysis of such electrocardiograms in children reported by Bengtsson [5], who studied twenty healthy children aged 1 to 12 years and thirty two with various heart lesions. At about the same time, Franke [22] studied 9 infants with congenital heart disease. Then followed the investigations of Huth & Kollmann [27] and Ambaldi et al. [1], which were based on single examination of 10 and 30 healthy infants aged 1 month to 12 years and 7 days to 1 year respectively. Thus, although this approach permits recording of semidirect leads from the left atrium and is of acknowledged value in the study of arrhythmias, very little data is available in children and none in the neonate.

This report is based on the findings on serial examination of 100 healthy newborns during the first week of life. Normal standards and variations encountered are presented.

Leads V4R, V1 to V6, 2V1, 2V2 and V (the latter were recorded at the right and left second intercostal space and at the tip of the sternal xyphoid process).

1 671443

Method

One hundred healthy infants were studied on the first, second, third and fifth or sixth day of life. Four were not examined on the first day. Two infants had a birth weight of 2410 g and 2480 g respectively; the remainder weighed more than 2500 g each. All were the products of presumably uncomplicated deliveries without maternal analgesia or anesthesia, were cephalic presentations and had delayed clamping of the umbilical cord. There were no twins, no Caesarean sections, and no known maternal illness. Other data on these infants has been published elsewhere [47–51]

For purposes of determining differences with age, analysis was restricted to 68 infants, 43 of whom were female, who had had four examinations each. These infants were divided into 4 groups, with an average gestational age of 41 weeks each, based on age of initial examination.

Group I. 30 minutes old or less (17 infants).
Group II. 33 to 60 minutes old (21 infants).
Group III. 65 minutes to 4 hours old (13 infants).
Group IV. 4½ hours old (17 infants).

All recordings were taken at a paper speed of 100 mm/sec on a 4-channel jet recorder by the author with an assistant. Standard bipolar extremity, augmented unipolar extremity, 10 precordial[1] and a series of unipolar esophageal and gastric leads were obtained. The esophageal electrode was made by soldering a german silver bead measuring ~ mm in diameter to a 37 cm length of well-insulated copper

This work was supported by grants from the American Heart Association, National Institutes of Health (07959 CV 1 T01 HD-166-01), International Cardiology Foundation and the Association for Aid to Crippled Children. Publication costs were obtained from National Institutes of Health grant 1 T01 HD-00166-01

UPPSALA 1967

Cremer [17] is generally credited with being the first to obtain esophageal leads. Since then, a number of experimental and clinical studies in adults have appeared—including those of Lieberson & Liberson [32], Brown [9], Helm et al. [26], Deglaude & Laubry [19], Nyboer [35], Myers & Klein [34], Kistin et al. [28], and Scherlis et al. [40]. However even in adults, normal values are based on relatively small numbers of healthy individuals. Not until 193_ was an analysis of such electrocardiograms in children reported by Bengtsson [5], who studied twenty healthy children aged 1 to 12 years and thirty-two with various heart lesions. At about the same time Franke [22] studied 9 infants with congenital heart disease. Then followed the investigations of Huth & Kollmann [27] and Anibaldi et al. [1], which were based on single examination of 10 and 30 healthy infants aged 1 month to 1_ years and 7 days to 1 year respectively. Thus, although this approach permits recording of semidirect leads from the left atrium and is of acknowledged value in the study of arrhythmias, very little data is available in children and none in the neonate.

This report is based on the findings on serial examination of 100 healthy newborns during the first week of life. Normal standards and variations encountered are presented.

Leads V4R, V1 to V8, 3V1, 3V2 and V (the latter were recorded at the right and left second intercostal space and at the tip of the sternal xyphoid process).

1 - 971444

Method

One hundred healthy infants were studied on the first, second, third and fifth or sixth day of life. Four were not examined on the first day. Two infants had a birth weight of 2410 g and 2480 g respectively; the remainder weighed more than 2500 g each. All were the products of presumably uncomplicated deliveries without maternal analgesia or anesthesia, were cephalic presentations and had delayed clamping of the umbilical cord. There were no twins, no Caesarean sections, and no known maternal illness. Other data on these infants has been published elsewhere [47–51].

For purposes of determining differences with age, analysis was restricted to 68 infants, 43 of whom were female, who had had four examinations each. These infants were divided into 4 groups, with an average gestational age of 41 weeks each, based on age of initial examination.

Group I. 30 minutes old or less (17 infants).
Group II. 35 to 60 minutes old (21 infants).
Group III. 65 minutes to 4 hours old (13 infants).
Group IV. 4½ hours old (17 infants).

All recordings were taken at a paper speed of 100 mm/sec on a 4-channel jet recorder by the author with an assistant. Standard bipolar extremity, augmented unipolar extremity, 10 precordial[1] and a series of unipolar esophageal and gastric leads were obtained. The esophageal electrode was made by soldering a german silver bead measuring mm in diameter to a 37 cm length of well-insulated copper

wire This was then drawn through a 2 mm wide polyethylene tube marked at 1 cm intervals. The central terminal of Wilson was used as the indifferent electrode Systolic blood pressure was recorded with the Ashworth modification of the xylol recorder [2] and heart volume using Lysholm-Jonsell's modification of Röhrer Kahlstorf's method as described by Lind [33] was measured on roentgenograms of the chest on the first and fifth or sixth day of life

Rapid paper speed essential for the rapid heart rates of infancy a magnifying lens of ×5 simultaneous recording of standard leads periodic testing of paper speed and use of an external voltmeter increased the accuracy of measurements. Time intervals were estimated to the closest 5 msec and amplitudes to the closest 0 5 mm (05 mV) and corrected for standardization Measurements were made in accordance with the recommendations of the Criteria Committee of the New York Heart Association [18]

Every effort was made to disturb the infants as little as possible However the extremities were always gently pinioned down as previously described prior to taking any recordings. As infants invariably regurgitated and/or became restless when swallowing the electrode this approach was not used Instead, once the infant was sucking on a pacifier without using local anesthesia the oesophageal electrode was gradually advanced a distance of 23 cm via the nares. In the first 53 infants the catheter was withdrawn at 1 cm stages from 23 to 3 cm (21 leads) Because changes occurred with even minor displacement of the electrode especially in peri-atrial leads in the remaining 47 infants additional one-half cm levels were obtained between 18 and 8 cm (total 31 leads) Fluoroscopic control of electrode position was not deemed justified, but the electrode was held in place and great care was exercised in repeatedly checking the position at the nares.

Nomenclature and Treatment of Data

After all the measurements had been made the entire material was re-read to ensure uniformity of classification. No method seems exact and reproducible partly because minor displacement of the oesophageal electrode may go undetected In this study atrial leads have been strictly defined as only those in which the *P* wave has a sharp intrinsic deflection To minimize error no borderline cases have been included. Leads obtained above and below this level are supra- and infra atrial leads. The latter are further subdivided according to appearance of the ventricular complex, i e leads resembling one or more precordial leads and/or Lead II or aVF are ventricular and those neither resembling ventricular nor atrial leads are transitional With passage of the electrode, a characteristic series of patterns is seen, but exact points of reference cannot be used as pattern types overlap

Although all leads are included in the analysis measurements of amplitude of deflections and duration of intervals are confined to leads obtained at the following levels (*a*) highest (*h*) intermediate (*i*) and lowest (*l*) *atrial* (*b*) 1 and 3 cm *above the highest atrial* (supra-atrial leads (*a*) and (*b*)) (*c*) 1 and 3 cm below the lowest atrial and at approximately

2 cm stages distally (infra-atrial leads ( ) (b) (c), (d) and (e)) By using a set distance from atrial leads, serial diffe rences with age can be evaluated to some xtent and subsequent studies may more easily be compared to this data. On the other hand using a set distance from the nares results in a wide scatter of levels, g., 10 cm from the nares is found from 1 to 7 cm below the lowest atrial lead.

Statistical Methods

Where the number of cases decreases, this is either because no lead was available at the designated level or because the recording was unsatisfactory

The standard deviation was calculated with the following formula.

$$s.D. = \sqrt{\frac{n\sum x^2 - (\sum x)^2}{n(-1)}}$$

As the distribution of amplitudes of the *Qp Rp/Sp* ratio and ventricular *QRS* comple t nds to be skew percentiles ha e been determined in preference to means nd tandard deviations.

The first quartile is the value of the

$$\frac{+1\text{th}}{4}$$

of the cases when they are arrayed from lowest to highest the median, the

$$\frac{+1\text{th}}{}$$

and the third quartile the

$$\frac{3(+1)\text{th}}{4}$$

case

Differences were investigated between the 4 groups of infants using the standard tests (student s t test, chi square) Where there were no differences, the groups were combined for investigation of differences between 2 groups or of the whole group at different ages.

Anatomy

In the newborn, the esophagus starts as the continuation of the pharynx at the cricoid cartilage opposite the body of the 4th cervical vertebra, extends a distance of about 9 or 10 cm and termina tes at the cardiac orifice of the stomach level with the 9th or 10th dorsal vertebra [12 42]. It is 4 to 5 mm wide (empty) and the cardia is stated to be located bout 17 cm from the teeth [4]. According to Caffey the normal adult curves (upper and lower third—slightly convex to left mid portion—convex to right) and constrictions (origin, aortic arch crossing of left bronchus and at diaphragm) are present during infancy but less well defined.

The esophagus lies in close proximity to the left atrium, and for this reason provides a simple method for recording of atrial complexes of higher amplitudes than with more remote leads. In adults, there has been some discussion as to whether the lower end of the esophagus is solely in relation w th the posterior basal wall of the left ventricle. Some believe that slight changes in cardiac position of the heart may bring the interventri cular sulcus or even the right ventricle into relation with the esophagus [28]; others, that the diaphragmatic segment may often be in closer contact with the

wire This was then drawn through a 2 mm wide polyethylene tube marked at 1 cm intervals. The central terminal of Wilson was used as the indifferent electrode Systolic blood pressure was recorded with the Ashworth modification of the xylol recorder [2] and heart volume using Lysholm-Jonsell's modification of Röhrer Kahlstorf's method as described by Lind [33] was measured on roentgenograms of the chest on the first and fifth or sixth day of life

Rapid paper speed, essential for the rapid heart rates of infancy a magnifying lens of $\times 5$ simultaneous recording of standard leads, periodic testing of paper speed and use of an external voltmeter increased the accuracy of measurements. Time intervals were estimated to the closest 5 msec and amplitudes to the closest 0 5 mm (0.05 mV) and corrected for standardization Measurements were made in accordance with the recommendations of the Criteria Committee of the New York Heart Association [18]

Every effort was made to disturb the infants as little as possible However the extremities were always gently pinioned down as previously described prior to taking any recordings. As infants invariably regurgitated and/or became restless when swallowing the electrode this approach was not used. Instead once the infant was sucking on a pacifier without using local anesthesia the esophageal electrode was gradually advanced a distance of 23 cm via the nares. In the first 53 infants, the catheter was withdrawn at 1 cm stages from 23 to 3 cm (21 leads) Because changes occurred with even minor displacement of the electrode especially in peri atrial leads in the remaining 47 infants, additional one half cm levels were obtained between 18 and 8 cm (total 31 leads) Fluoroscopic control of electrode position was not deemed justified but the electrode was held in place and great care was exercised in repeatedly checking the position at the nares.

Nomenclature and Treatment of Data

After all the measurements had been made the entire material was re-read to ensure uniformity of classification. No method seems exact and reproducible partly because minor displacement of the esophageal electrode may go undetected. In this study atrial leads have been strictly defined as only those in which the *P* wave has a sharp intrinsic deflection. To minimize error no borderline cases have been included Leads obtained above and below this level are supra and infra atrial leads. The latter are further subdivided according to appearance of the ventricular complex i.e leads resembling one or more precordial leads and/or Lead II or aVF are ventricular and those neither resembling ventricular nor atrial leads are transitional With passage of the electrode a characteristic series of patterns is seen, but exact points of reference cannot be used as pattern types overlap

Although all leads are included in the analysis measurements of amplitude of deflections and duration of intervals are confined to leads obtained at the following levels. (*a*) highest (*h*) intermediate (*i*) and lowest (*l*) atrial, (*b*) 1 and 3 cm above the highest atrial (supra-atrial leads (*a*) and (*b*)) (*c*) 1 and 3 cm below the lowest atrial and at approximately

2 cm stages distally (infra-atrial leads (a) (b) (c), (d) and (e)). By using a set distance from atrial leads, serial differences with age can be evaluated to some extent and subsequent studies may more easily be compared to this data. On the other hand, using a set distance from the nares results in a wide scatter of levels, e.g. 19 cm from the nares is found from 1 to 7 cm below the lowest atrial lead.

Statistical Methods

Where the number of cases decreases, this is either because no lead was avail ble at the designated level or because the recording was unsatisfactory

The standard deviation was calculated with the following formula.

$$s.D. = \sqrt{\frac{n\sum x^2 - (\sum x)^2}{n(n-1)}}$$

As the distribution of amplitudes of the Qp Rp/Sp ratio and entricular QRS comple tends to be skew percentiles have been determined in preference to mean and standard deviations.

The first quartile is the value of the

$$\frac{n \quad 1\text{th}}{4}$$

of the cases when they are arrayed from lo est to highest the median, the

$$+ 1\text{th}$$

and the third quartile the

$$\frac{3(\quad 1)\text{th}}{4}$$

case

Differences were investigated between the 4 groups of infants using the standard tests (student s t test, chi square) Where there were no differences, the groups were combined for investigation of differences between 2 groups or of the whole group at different ages.

Anatomy

In the newborn, the esophagus starts as the continuation of the pharynx at the cricoid cartilage opposite the body of the 4th cervical vertebra, extends a distance of about 9 or 10 cm and termina tes at the cardiac orifice of the stomach, level w th the 9th or 10th dorsal vertebra [12 42]. It is 4 to 5 mm wide (empty) and the cardia is stated to be located about 17 cm from the teeth [4] According to Caffey the normal adult curves (upper and lower third—slightly convex to left mid portion—convex to right) and constrictions (origin, aortic arch crossing of left bronchus and at diaphragm) are present during infancy but less well defined.

The esophagus lies in close proximity to the left atrium, and for this reason, provides a simple method for recording of atrial complexes of higher amplitudes than with more remote leads. In adults, there has been some discussion as to whether the lower end of the esophagus is solely in relation with the posterior basal wall of the left ventricle. Some believe that slight changes in cardiac position of the heart may bring the interventricular sulcus or even the right ventricle into relation with the esophagus [28]; others, that the diaphragmatic segment may often be in closer contact with the

inferior vena cava or the posterior caudad segment of the right atrium [29] still others that neither of these chambers are in contiguity with the esophagus [10]. However in newborns, the posterior part of the inferior or diaphragmatic surface of the heart is stated to be formed solely by the atrial portion of the heart [38]

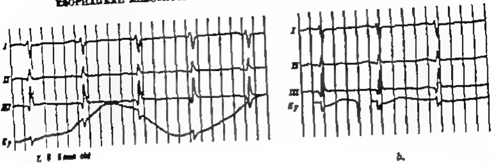
Artefacts

It seems fair to state that the number of artefacts or errors in labelling of esophageal leads exceed those encountered with routine electrocardiographic leads. This is not to say that many records cannot be obtained which are essentially artefact-free However in certain regions of the esophagus, notably near the atrium minimal displacement of the electrode may result in significant changes in the appearance of the complex Repeated careful checking of location, with an assistant holding the electrode exactly in place reduces this problem somewhat On the other hand when the electrode is in the upper esophagus, infants are often able to extrude the catheter with a forced expiration making its exact location in this region difficult to determine Although the location of the esophageal electrode was not determined by fluoroscopy it seems unlikely that curling of the catheter occurred because (1) the typical progression of complexes on withdrawal of the electrode was observed in every infant (2) there is a direct correlation ($r = 0.413$ $p < 0.001$) between the level of the transitional lead and the infant's length and (3) the catheter though flexible does not have a tendency to curl However in a few cases described by Kistin *et al.* [28] roentgenograms show the esophageal tube to be doubled up in the esophagus

The most common artefacts are baseline wandering *A–C* interference and variable amplitude. The incidence of a wandering baseline in various leads was not determined but was seen in most leads at some time This artefact can be reduced though not eliminated, by having the infant lie as quietly as possible. Both deep respirations and sucking seem to be mainly responsible for this finding but in some instances both may be present with a level baseline Sucking effects are probably greater in higher esophageal leads they are more irregular and cause sharp dips while deep respirations are regular and wavy and more common near the diaphragm (Fig 1) *A–C* interference is not uncommon in gastric and low esophageal leads, especially after feeding and is probably induced by contact with gastric contents. Slight withdrawal of the electrode improves the recording

Variations in amplitude of the *P* and *QRS* deflections are fairly common and also appear to be related to respirations. Such variations occur even in the absence of a wandering baseline and often affect the *P* wave more than the ventricular *QRS* complex

According to Brown, all electrodes and especially small metal ones are subject to polarization effects. Such effects become significant only when they are large which is uncommon. Then measurements of intervals are little affected but significant alterations in amplitude occur especially in the returning stroke from any sharply developed peak. These effects



a. b.

Fig. 1 Artefacts recorded with an esophageal lead 7 cm from the nares in 5-minute-old infant. (a) deep respirations—very regular baseline; (b) sucking—sudden disappearance of baseline. (Paper speed 100 mm/sec; distance between vertical time lines = 50 msec; tracing redrawn to scale.)

were not investigated, but as Brown states that they are rare it seems unlikely that they are of significance in the present study.

Artefacts are probably more frequent in adults. These have been variously ascribed to peristalsis, respirations, swallowing, poor contact, motion of the heart [28], transmitted pulsations from the aorta [30], and diaphragmatic contractions [19]. In this investigation, no constant artefact was observed from peristalsis, nor could movements of the heart or from transmitted pulsations be recognized.

Levels

Supra-atrial leads 1 and 3 cm above the highest atrial leads, as well as highest and intermediate atrial leads, are recorded at a mean of 10, 12, 13, and 14 cm from the nares. These levels do not change with age. On the other hand, lowest atrial and infra-atrial leads are initially recorded at mean levels of 15, 15.5, 17.5, 19, 21 and 23 cm from the nares, but at the end of the week are found at a slightly lower level, i.e., 15.5, 16.5, 18.5 and 19.5 cm respectively, little change having occurred in the lowest two leads. This shift with age is also present in transitional leads

TABLE 1 *Mean distance (cm) from the nares of esophageal leads on the first and fifth or sixth day of life.*

Groups combined as no significant differences present. Supra-atrial leads a and b are recorded 3 and 1 cm above the highest atrial lead. h, highest; i, intermediate; l, lowest atrial leads. Infra-atrial leads a, b, c, d, and e are recorded approximately 1, 3, 5, 7 and 9 cm below the lowest atrial lead.

	Supra-atrial		Atrial			Infra-atrial				
Day	a	b	h	i	l	a	b	c	d	e
1	9.94	11.94	12.63	13.70	14.97	15.63	17.56	19.33	1.30	23.00
5–6	10.07	12.07	13.04	14.17	15.[illegible]	16.40	18.40	19.92	21.71	23.00

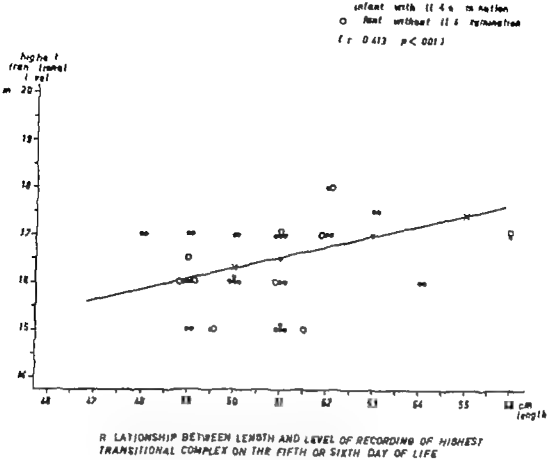


Fig — There is a direct relationship between the infant length and level of recording of the highest transitional complex. This is also true of mid-atrial and ventricular leads as defined in this study

which by definition are not dependent on location of atrial leads, suggesting that this is not a spurious finding (Table 1)

The mid atrial level varies directly with the length of the infant and histograms show a similar relationship between length and transitional and ventricular leads That is the longer the infant the lower the level of the respective lead (Fig 2) A similar trend between surface area and level of atrial recording is also present i e the greater the surface area the lower the level of the atrial leads However the area over which atrial leads are recorded in each infant is influenced not by length but by age In other words, these leads are inscribed over an area extending from a single point to 1 cm in 21 of 68 infants initially as compared to 5 of 68 infants at the end of the week and over an area from 2.5 to 4 0 cm in 18 infants initially as compared to 34 of 68 infants later The smaller the initial area from which atrial leads are obtained, the more likely the increase with age. Thus, increases occurred in 31 of 35 infants in whom atrial leads were obtained from an area of 1 5 cm or less initially in contrast to 12 of 34 infants with an area of 2 0 cm or more initially

As mentioned earlier the classification of atrial leads has been strictly based on presence of a sharp intrinsic deflection. This necessarily reduces the area from which atrial leads are obtained and affects the level of supra- and infra-atrial leads. The latter two regions are directly dependent on location of atrial leads, a possible source of error in serial studies. But the location of atrial leads, as shown above is dependent on the infant's age, length, surface area, as well as the direction of the P vector.

Heart Rate

The true resting heart rate is difficult to determine in the newborn because minimal stimuli may induce significant changes. Only continuous monitoring of heart rate in a sound proof room can be considered entirely satisfactory for this purpose. With this in mind, it is thought to be of interest to mention some of the findings encountered here because of the relatively long recording period, the attention paid to disturbing the infants as little as possible and the essentially physiological state of these infants at birth.

On the first day of life heart rate ranged from 74 to 200 with a mean of 123 beats/minute. There was little change in rate during the next few days, but at the end of the week the mean rate increased to 137 beats/minute.

Sinus arrhythmia was not uncommon especially after the first day of life and was not limited to infants with the slowest heart rates. Several infants had a transient wandering pacemaker in one or two leads, one of them also had a single atrial

Table 2. *Heart rate in esophageal leads showing mean, standard deviation and range in 68 healthy infants during the first week of life (groups combined).*

* One of these infants also had a single atrial premature contraction.

r^1, range in atrial leads; r^2, range in other esophageal leads; s.a., sinus arrhythmia; w.p., wandering pacemaker.

premature contraction. (Table 2.) Still another infant, not included in the table developed a persistent wandering pacemaker on his last two examinations. Two other infants had complete right bundle-branch block and constant Wolff-Parkinson-White syndrome respectively on the first and second day of life (40). These findings were still present when they were reexamined at the age of one year.

It seems clear that mild arrhythmias are relatively common and that their presence cannot be adequately evaluated without considerably longer recording periods. As noted on page 30 brief shifts in pacemaker may be induced by the esophageal electrode itself.

On the first day of life rates are relatively rapid immediately after birth, become slower during the first hour and then gradually increase, but not to initial values. The increases at the end of the week have also been observed by Contis & Lind (15), but the mechanism for this change is not clear.

P Wave Duration

Measurements of the longest P wave duration P–R interval and heart rate were generally made in high or mid-atrial leads with a Qp wave and in lead V_2. Absence of the Qp wave is more commonly associated with shorter P waves Exact measurement of P wave duration is hampered by slurring of the Qp and Sp waves. The former is common while the latter is less frequent

In most leads measurements of P and P–R intervals vary in each lead as well as with each complex This often amounts to 10 or 20 msec but can be significant as Caceres & Kelser [11] have shown. Furthermore in such a lead as V_2, accuracy of measurement of the P wave at least in the newborn seems highly questionable because of the frequency of a low notch often with an initial isoelectric portion. This is probably true of all leads *from the right precordium* Left chest leads may be more satisfactory for accurate measurement of P wave duration in this group but greater amplification is needed *In the absence of several si*multaneous leads it may be still more difficult or impossible to determine exact onset or termination of waves.

On the first day of life the duration of the P wave in esophageal leads is relatively shorter after birth reaches a maximum at 35 to 60 minutes and then gradually decreases *throughout* the rest of the day More specifically mean values increase from 60 to 69 ($p <$ 01) and then decrease to 63 and 59 msec in the 4 groups *respectively* Median values are almost identical The P–R interval also tends to be longer in Group II infants but is not

fifth or sixth day of life. A similar relationship between duration of the *P* wave in lead I and the esophageal lead is only present on the first day of life in infants one hour of age or less, but not subsequently No relationship could be demonstrated bet een the size of the largest intrinsic deflection and the dura tion of this interval.

On the first day of life 2 of 17 infants in Group I as compared to 8 of 17 infants in Group IV had a longer *P* wave duration in atrial leads than in lead II. At the end of the week, the distribution was similar for all 68 infants with no difference in the majority and an equal number of longer *P* w ves in either lead II or the atrial lead (not exceeding 30 msec but generally $< \pm 15$ msec).

Recordings of lead I and esophageal leads were not taken simultaneously but it was thought to be of interest to also compare *P* wave duration in these leads. In this case, on the first day of life, 12 of 17 infants (70 %) in Group I had longer *P* waves in atrial leads as compared to 5 of 17 infants (31 %) in Group IV At the end of the week, the distribution was similar for all 68 infants. 40 (59 %) had longer *P* waves in atrial leads, 17 (25 %) longer values in V_1, and no difference was present in the remain der

The difference in time of onset of the *P* wave in simultaneously recorded atrial esophageal leads, preferably with a *Qp* wave, and in lead II was determined. Correction was made for any difference in timing between the channels. Questionable cases were classified as no dif ference. Absence of a *Qp* wave was relatively uncommon but did not appear to influence the findings. On the first day of life, onset of the *P* wave was ear lier in the esophageal lead in 17 % of the infants in Group I as compared to 64 % of those in Group IV ($p < .05$). By the end of the week, the esophageal *P* wave was earlier in 23 (34 %) later in 15 (22 %) and there was no difference in the majority [30] (44 %) of infants. These results are in accord with the abovementioned differences in *P* wave duration in simultaneously recorded lead II and the esophageal lead.

In adults, Copeland and associates [16], using a paper speed of 25 mm/sec, found that the trial deflection in esophageal leads is of *significantly shorter* duration and of later onset *than in lead* II. In their opinion, an esophageal electrode located in the vicinity of atrial transition (equiphasic *P* wave) is insensitive to the initial and terminal forces

P Wave Duration

Measurements of the longest P wave duration, P–R interval and heart rate were generally made in high or mid-atrial leads with a Qp wave and in lead V_1. Absence of the Qp wave is more commonly associated with shorter P waves. Exact measurement of P wave duration is hampered by slurring of the Qp and Sp waves. The former is common while the latter is less frequent

In most leads measurements of P and P–R intervals vary in each lead as well as with each complex This often amounts to 10 or 20 msec, but can be significant as Caceres & Kelser [11] have shown. Furthermore in such a lead as V_1, accuracy of measurement of the P wave at least in the newborn seems highly questionable because of the frequency of a low notch often with an initial isoelectric portion *This is probably true of all leads* from the right precordium Left chest leads may be more satisfactory for accurate measurement of P wave duration in this group but greater amplification is needed. In the absence of several simultaneous leads, it may be still more difficult or impossible to determine exact onset or termination of waves.

On the first day of life the duration of the P wave in esophageal leads is relatively shorter after birth reaches a maximum at 35 to 60 minutes and then gradually decreases throughout the rest of the day More specifically mean values increase from 60 to 69 ($p < 01$) and then decrease to 63 and 59 msec in the 4 groups respectively Median values are almost identical The P–R interval also tends to be longer in Group II infants but is not

fifth or sixth day of life. A similar relationship between duration of the P wave in lead V and the esophageal lead is only present on the first day of life in infants one hour of age or less, but not subsequently. No relationship could be demonstrated between the size of the largest intrinsic deflection and the duration of this interval.

On the first day of life 2 of 17 infants in Group I as compared to 8 of 17 infants in Group IV had a longer P wave duration in atrial leads than in lead II. At the end of the week, the distribution was similar for all 68 infants with no difference in the majority and an equal number of longer P waves in either lead II or the atrial lead (not exceeding 30 msec, but generally $\leq \pm 15$ msec).

Recordings of lead V and esophageal leads were not taken simultaneously but it was thought to be of interest to also compare P wave duration in these leads. In this case on the first day of life 12 of 17 infants (70%) in Group I had longer P waves in atrial leads as compared to 5 of 17 infants (31%) in Group IV. At the end of the week, the distribution was similar for all 68 infants. 40 (59%) had longer P waves in atrial leads, 17 (25%) longer values in V_{1}, and no difference was present in the remainder.

The difference in time of onset of the P wave in simultaneously recorded atrial esophageal leads, preferably with a Qp wave and in lead II was determined. Correction was made for any difference in timing between the channels. Questionable cases were classified as no difference. Absence of a Qp wave was relatively uncommon but did not appear to influence the findings. On the first day of life, onset of the P wave was earlier in the esophageal lead in 17% of the infants in Group I as compared to 64% of those in Group IV ($p < 0.05$). By the end of the week, the esophageal P wave was earlier in 23 (34%) later in 15 (22%) and there was no difference in the majority [30] (44%) of infants. These results are in accord with the abovementioned differences in P wave duration in simultaneously recorded lead II and the esophageal lead.

In adults, Copeland and associates [16], using a paper speed of 25 mm/sec, found that the atrial deflection in esophageal leads is of significantly shorter duration and of later onset than in lead II. In their opinion, an esophageal electrode located in the vicinity of atrial transition (equiphasic P wave) is insensitive to the initial and terminal forces

P Wave Duration

Measurements of the longest P wave duration, P–R interval and heart rate were generally made in high or mid-atrial leads with a Qp wave and in lead V. Absence of the Qp wave is more commonly associated with shorter P waves. Exact measurement of P wave duration is hampered by slurring of the Qp and Sp waves. The former is common while the latter is less frequent.

In most leads, measurements of P and P–R intervals vary in each lead as well as with each complex. This often amounts to 10 or 20 msec but can be significant, as Caceres & Kelser [11] have shown. Furthermore in such a lead as V_1, accuracy of measurement of the P wave at least in the newborn, seems highly questionable because of the frequency of a low notch often with an initial isoelectric portion. This is probably true of all leads from the right precordium. Left chest leads may be more satisfactory for accurate measurement of P wave duration in this group but greater amplification is needed. In the absence of several simultaneous leads it may be still more difficult or impossible to determine exact onset or termination of waves.

On the first day of life, the duration of the P wave in esophageal leads is relatively shorter after birth, reaches a maximum at 30 to 60 minutes and then gradually decreases throughout the rest of the day. More specifically mean values increase from 60 to 69 ($p < 01$) and then decrease to 63 and 59 msec in the 4 groups respectively. Median values are almost identical. The P–R interval also tends to be longer in Group II infants but is not statistically significant. By the second day mean values in all groups range from 54 to 60 msec and further decrease to 40–53 msec at the end of the week. (Table 3, 4.) Mean individual decreases are greatest from the first to the second day, less from the second to the third, least from the third to the fifth or sixth day of life and most marked in infants in Groups II and III, those with the longest initial values. The findings are essentially similar in simultaneously recorded leads II and V_1. Neither the changes in duration of the P wave on the first day of life nor during the week were found to be related to changes in heart rate. Likewise significant decreases in duration of the P–R interval with age independent of changes in heart rate also occur and median values on the first and last examination are almost identical with the means.

Scattergrams show a linear relationship between P wave duration in atrial leads and in lead II both on the first and the

fifth or sixth day of life. A similar relationship between duration of the P wave in lead V and the esophageal lead is only present on the first day of life in infants one hour of age or less, but not subsequently. No relationship could be demonstrated between the size of the largest intrinsic deflection and the duration of this interval.

On the first day of life, 2 of 17 infants in Group I as compared to 8 of 17 infants in Group IV had a longer P wave duration in atrial leads than in lead II. At the end of the week, the distribution was similar for all 68 infants with no difference in the majority and an equal number of longer P waves in either lead II or the atrial lead (not exceeding 30 msec but generally ≤ ± 15 msec).

Recordings of lead V and esophageal leads were not taken simultaneously but it was thought to be of interest to also compare P wave duration in these leads. In this case, on the first day of life, 12 of 17 infants (70%) in Group I had longer P waves in atrial leads as compared to 5 of 17 infants (31%) in Group IV. At the end of the week the distribution was similar for all 68 infants: 40 (59%) had longer P waves in atrial leads, 17 (25%) longer values in V_1, and no difference was present in the remainder.

The difference in time of onset of the P wave in simultaneously recorded atrial esophageal leads, preferably with a Qp wave and in lead II was determined. Correction was made for any difference in timing between the channels. Questionable cases were classified as no difference. Absence of a Qp wave was relatively uncommon but did not appear to influence the findings. On the first day of life, onset of the P wave was earlier in the esophageal lead in 17% of the infants in Group I as compared to 64% of those in Group IV ($p < .05$). By the end of the week, the esophageal P wave was earlier in 23 (34%), later in 15 (22%) and there was no difference in the majority [30] (44%) of infants. These results are in accord with the abovementioned differences in P wave duration in simultaneously recorded lead II and the esophageal lead.

In adults Copeland and associates [16] using a paper speed of 25 mm/sec, found that the atrial deflection in esophageal leads is of significantly shorter duration and of later onset than in lead II. In their opinion, an esophageal electrode located in the vicinity of atrial transition (equiphasic P wave) is insensitive to the initial and terminal forces

of atrial depolarization According to Brown P wave duration in esophageal electrocardiograms is usually longer than that in conventional leads But he includes initial positive and late negative waves which in this study were often not considered to be a true part of the P wave He also mentions that a small wave may precede onset of the P wave in lead II

Q Rp Time

The Q–Rp time in atrial leads is measured from the take-off of the Qp to the peak of the Rp wave The duration of this interval varies at different levels but tends to be greater in higher leads also noted by Brown On the first day of life mean values were longer in highest atrial leads and tended to be longer at all three levels in infants in Groups II and III although the latter difference was not statistically significant As in the case of P wave duration significant decreases also occur during the first week of life ($p < 001$) unrelated to changes in heart rate That is on the first day of life at the intermediate atrial level 18 of 56 infants have an interval of 40 msec or more as compared to none of 58 infants at the end of the week (Table 4)

Using scattergrams, the duration of this interval was not found to be related to the size of the largest intrinsic deflection heart volume nor the level of the systolic blood pressure A direct linear relationship between P wave duration and the Q–Rp interval in the intermediate atrial lead is present in all groups only on the first day of life Subsequently there is only a tendency to such a relationship in infants in Groups III and IV

P Wave Amplitude[1]

When the electrode is placed in the stomach and withdrawn, the contour direction and amplitude of the P wave gradually change as the atrial level is approached. The P wave—initially small round and positive—increases in amplitude becomes diphasic, and often of considerable magnitude with or without an initial Qp and then low round and negative of gradually decreasing amplitude The exact site of these changes varies, but tends to begin abruptly at the atrial level. As mentioned earlier variations in amplitude are not uncommon and are presumably respiratory

In some cases, the P wave remains negative even below the atrium In others, the intrinsic deflection is of such low amplitude as to interfere with exact determination of the atrial level or else as is commonly found, it becomes isoelectric in the lowest atrial leads or slightly below this point. Such low amplitude P waves have also been observed in adults by Brown who attributes them in part to electrical events occurring in the neighboring inferior vena cava.

An initial sloping positive wave not uncommonly precedes the Qp wave Occasionally it has a sharper contour and seems to be part of the atrial P wave More often it is inscribed with termination of the T wave or the latter half of the U wave in simultaneously recorded standard bi polar leads. Just below the atrial level, instead of a Qp wave, an initial

[1] QSp waves are listed with the Sp wave in supra-atrial and highest atrial leads.

Cases with *Qp* wa of 0.5 mm or more.

small positive wave more like a notch on the upstroke of the *Rp* may be seen. This wave may interfere with measurement of *P* wave amplitude.

The *Qp* wave is often slurred, but can vary from slurred to sharp even in the same lead—a possible respiratory effect—thereby causing considerable difficulty in measurement of duration of the atrial *P* wave. This wave is of greatest amplitude at or slightly above the atrial level. It never exceeds 0.25 mV and may be seen only as an early notch on a broad peaked negative wave. In a few cases, it is more prominent in the mid-atrium, and may not be present in leads above this. On the first day of life, the differences between medians of younger and older infants, i.e. those older than one hour of age are just short of significant at highest and lowest atrial levels. In lowest atrial leads, a *Qp* wave is present in only *one-fifth of the infants*. (Table 5).

At birth, the mean amplitude of the Rp wave in intra-atrial lead (d) is slightly lower in infants in Groups I and II (just short of significant). However increases in most leads, apart from the highest *atrial lead, are greater in younger infants* from the first to the last examination but only of *statistical significance in lowest* atrial and intra-atrial leads (*c*) and (*d*). About one-third of the infants at birth and at the end of the week have an *Rp* in highest atrial leads while only seven of them did not have this wave at some time during the first week of life in intermediate atrial leads. High amplitudes are common with a maximum of 1.2 mV on the first day and of 0.9 mV at the end of the week. Although the highest values of the *Rp* wave are recorded at the latter level, relatively large amplitudes are also seen in lowest atrial leads. As the distribution of values was skew for *Rp* in highest atrial and *Sp* in lowest atrial leads, medians were also calculated, but no significant differences were noted.

Significantly lower mean values of the *Sp* wave are recorded *initially* in

TABLE 6A R_p and S_p amplitudes in 1/10 mV in esophageal leads showing range mean and standard deviation during the first week of life.

largest intrinsic, positive and negative waves in all recorded leads were also analysed. The largest intrinsic deflection was measured from the peak of the *Rp* wave to the peak of the *Sp* wave. The findings are similar. That is, lower mean[1] and maximum values are recorded in infants less than one hour of age. Increases from the first to the last examination tend to be limited to younger infants. The size of the deflections may be of considerable magnitude but the range is wide. Bengtsson maximum normal value of 0.6 mV was not infrequently exceeded. (Table 7.) There appears to be a direct relationship between the size of the largest intrinsic deflection and the amplitude of the *P* wa in lead II, that is, the larger the intrinsic deflection, the larger the *P* wave amplitude in lead II, but only on the first day of life ($p<.03$). The size of this deflection was, however not found to be related to any other tested parameter such as the infant weight, systolic blood pressure, heart volume nor as mentioned earlier duration of the *P* wave.

The *Rp/Sp ratio* was also determined in both intermediate and lowest atrial leads. In accord with the finding of significantly lower amplitude *Sp* waves in infants less than one hour of age these infants also tend to have a higher ratio in both leads on the first day. From the first to the last examination, a slight increase in median is only found in older infants ($p<.05$). As in adults [35], lower ratios are found in the higher lead, although newborns have lower amplitude *Rp* and higher amplitude *Sp* waves in atrial leads [28]. (Table 8.)

Additional later waves may also be present. Nine of one hundred infants had a late *r* with or without an *s*, at some time during the first week. In 7 this finding was confined to the lowest atrial and in 2 to the intermediate atrial lead. There was no other associated finding.

Direction of P Waves

In supra-atrial leads, all infants have a negative *P* wave both at birth and at the end of the week. Initially in the highest atrial lead, the majority of infants in Group I have diphasic w ves while the majority of infants in Group IV have negative *P* waves. The latter is also the case at the end of the week. In intermediate atrial leads, both initially and later all infants have diphasic *P* waves. This is also true of Group IV infants in lowest atrial leads on the first day of life although more than a quarter of the youngest infants have a positive wave in this lead.

[1] But just short of statistical significance.

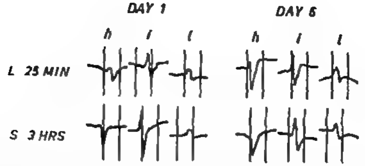

Fig 3. Esophageal P waves at highest (h) intermediate (i) and lowest (l) atrial levels. On the first day of life the amplitude of the P wave tends to be lower in younger than in older infants. At the end of the week, amplitudes are similar (tracing retouched).

infants less than one hour of age in supra-atrial (b) and atrial (h) leads ($p < .05$) but the same trend is present in intermediate and lowest atrial leads. Presumably for this reason individual and group increases in amplitude at the end of the week are either greater in, or limited to infants less than one hour of age on initial examination These changes with age are of statistical significance in supra-atrial (a) (b) and atrial (h) leads. As in the case of

But just short of statistical significance.

the Rp wave maximum values are recorded at the intermediate atrial level although large amplitudes also occur in highest atrial leads. The greatest Sp wave recorded at this level was 1.2 mV in a single infant on the third day of life In general amplitudes are smaller in lowest atrial leads. Below this level Sp waves are very uncommon. (Table 6 Fig 3)

As the greatest amplitude P waves are not necessarily seen in these leads the

Immediately below the atrium with few exceptions as noted above P waves are positive

The Ventricular QRS Complex[1]

Q Wave[2]

During the first few days Q waves are often not present in lowest infra-atrial leads. From the first to the last examination, the incidence of Q waves in these leads increases. There is little change in amplitude over this period although there

[1] The influence of the electrical axis and electrical position of the heart on the ventricular complex was not determined because only one infant in the first day of life had left axis deviation and horizontal position. Moreover no significant change in electrical axis occurred during the first week.

[2] In supra-atrial, atrial and high infra-atrial leads, Q and QS waves are listed with the S waves and R waves following an initial Q wave are listed as R′ Below this level initial negative deflections are listed as Q waves after a definite change in pattern has occurred and/or Q waves have significantly decreased in amplitude to 0 5 mV or less.

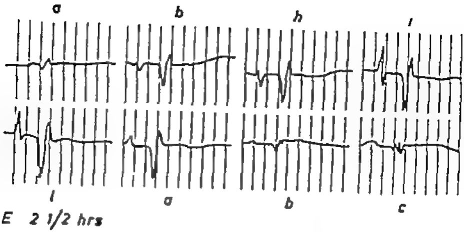
Cases with R waves of 0.5 mm or more

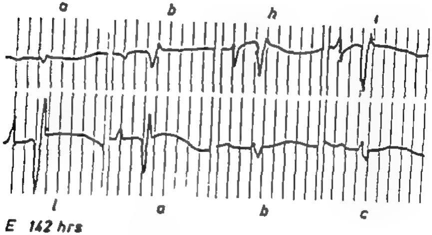
R waves following an initial deep Q wave are listed as R′

p Refers to significant differences from day 1 to 5–6

Figures in parentheses indicate minimum and maximum values in infants without all 4 examinations.



a.



b.

Fig. 4 Esophageal leads taken at supra-atrial (a b) atrial (h, i, l) and infra-atrial (a, b,) levels at ½ hours and at 14 hours. Note initial absence of an wave in upra-atrial lead (a), lower amplitude of the Q wave in trial leads (i, l) and appearance of $ST-T$ segment (These esophageal leads were aligned and then redrawn without modification.)

is a slight tendency to increase ($p < 05$) For the most part, larger deflections are seen in more proximal leads. (Table 9)

R Wave

Absence of an initial R wave 3 cm above the highest atrial lead is relatively common during the first few days of life—i e. 35 of 68 infants do not have this wave initially as compared to 10 of 68 infants at the end of the week The amplitude of this deflection tends to increase slightly with age Below this level an initial R wave is seldom seen.

In infra-atrial leads, R waves tend to be of greater amplitude in more distal leads and the highest values are more often recorded on the second or third day of life. From the first to the last examination, there is a tendency to small increases in proximal and decreases in distal leads ($p < 01$) (Table 10)

The amplitude of the Q and R waves exceeds that reported in adults [2] This has also been noted by Anibaldi *et al*

Cases with S wave of 0.5 mm or more.
Q and QS waves in these leads are included.
p Refers to significant differences from day 1 to 5–6.
Figures in parentheses indicate minimum and maximum values in infants *without* all 4 examinations.

finding was present at birth and at the end of the week in one infant and only at the end of the week in the other.

A QR pattern, characteristic of atrial leads, was seen in 6 infants 2 cm above the highest atrial and in 3 infants 1 cm below the lowest atrial lead, but not present at these levels in any infant at the end of the week. In other words, the area over which this complex is inscribed decreases. Four infants did not have a QR in any lead at birth as compared to 11 infants at the end of the week.

A qr in supra-atrial leads was seen in 3 infants in Groups I and II initially. It persisted in one until the end of the week and was first noted in another at the end of the week, although it may have been present earlier, an insufficient number of higher leads being available.

Unlike adults who have either a QS or QR in atrial leads (28), only 7 infants had a QS on the first day of life. Those one hour old or less tended to have this pattern in the highest atrial or 1 cm above this lead. This finding persisted in 2 infants at the end of the week. These infants were among the few (1 %) who did not have a secondary r wave in supra-atrial leads at the end of the week, even though some had had it earlier.

The incidence of deep S waves (not including QS waves) at any level increases with age, i.e., they are present in 31 infants on the first day as compared to 50 of 68 infants at the end of the week.

Although patterns vary significantly at different levels and to some extent on different days during the week, they are sufficiently characteristic to permit recognition of the approximate location of the lead.

Resemblance Between Esophageal and Routine Electrocardiographic Leads

Determination of resemblance of esophageal leads to the other 16 leads (standard bipolar, unipolar and precordial) has been fairly strictly interpreted, requiring P and T waves in the same direction as well as relatively similar amplitudes and ratios of the R and S waves. Therefore, the number of esophageal leads not resembling any other lead is probably greater in this study. As there did not appear to be any significant differences, the groups were combined for analysis.

The majority of leads adjacent to the atrium tend not to resemble any lead, while those above the atrium resemble lead aVR more than any other, but are seldom identical. In only a few instances does the QRS complex of supra-atrial leads resemble leads I, aVL or V_6. Little change takes place during the week. Scattergrams relating the R/S ratios* in lead aVR and supra-atrial lead (s) also suggest a direct linear relationship, especially at the end of the week. During this period little change in the ratio is found in the esophageal lead, but the ratio decreases significantly in lead aVR (i.e. a ratio of 2:1 or more is present in 24 infants initially as compared to 8 of 68 infants at the end of the week).

In the lead immediately below the atrium on the first day, only 6 of 67 infants have a pattern resembling some other lead, i.e., III, aVF and II in this order. At the end of the week, 13 of 68 infants have a pattern resembling either lead aVF or III.

* The late R was used in determining the ratio in both leads.

S Wave[1]

In supra-atrial and atrial leads values are generally higher in Group I and II infants initially (but not of statistical significance) and the amplitude increases gradually during the first week of life ($p < 01 - < 001$)

In infra-atrial leads amplitudes tend to be lower in younger infants (Groups I and II) initially but again not of statistical significance and gradually decrease during the week in infra-atrial lead (*a*) ($p < 001$) Absence of this wave is not uncommon 3 to 5 cm below the lowest atrial lead. (Table 11)

R'

On the first day in atrial leads and the lead immediately below the atrium amplitudes are lower (though not significantly) in infants in Groups I and II The size of these deflections increases in the middle of the week and then decreases again but is significant only in atrial leads (*h* *i*) in older infants. Progressive increase in size of this wave occurs with passage of the electrode more distally to lowest atrial and infra-atrial leads. (Table 12) In supra-atrial and mid atrial leads the R'/S or R/Q ratio is generally less than 1 0 In infra atrial lead (*a*) a ratio of 2 0 or more was seen in 10 infants at the end of the week In infra-atrial lead (*d*) and/or (*e*) 3 infants had a Q of 0 4 mV or more in 2 the voltage of the Q exceeded 25% of that of the R which in adults is often ascribed to myocardial infarction [28] (Fig 4)

QRS Patterns

For purposes of determining changes in patterns deflections measuring 4 5 mm (0 45 mV) or less are arbitrarily classified as a small *q* *r* or *s* wave As the electrode is advanced the following complexes are more commonly registered in the order mentioned

1 Supra-atrial level:
- *qr* or *rsr* — 3 to 5 cms from the nares.
- *rSr*
- *rSR* — proximal to the atrium.

2 Atrial level:
- *Qr*
- *QR*

3 Infra-atrial level[2]:
- *QR* — 1 cm below the atrium
- (*q*)*Rs* or (*q*)*R* — 3 to 5 cms below the atrium
- (*q*)*RS* — lowest leads.

Distinctive complexes are therefore registered at these 3 main levels, although some overlap of patterns in adjoining regions is common. Apart from atrial leads however there is considerable variation in appearance of complexes. This is most marked 3 to 5 cm below the atrium, the same area in which the greatest decrease in amplitude of deflections also occurs.

With few exceptions, if the initial deflection is a small *r* wave in higher supra-atrial leads an initial small *q* wave is seen in gastric leads, and vice versa.

The only 2 infants with a *qR* in supra-atrial leads are also the only infants with an *rS* in infra-atrial leads. In both instances the latter complex resembles that found in leads II and aVF and in one infant it is also present in lead aVL. This

---

[1] See p 18 note 2.

[2] Parentheses indicate that the *q* wave may or may not be present

finding was present at birth and at the end of the week in one infant and only at the end of the week in the other

A QR pattern, characteristic of atrial leads, was seen in 6 infants 3 cm above the highest atrial and in 3 infants 1 cm below the lowest atrial lead, but not present at these levels in any infant at the end of the week. In other words the area over which this complex is inscribed decreases. Four infants did not have a QR in any lead at birth as compared to 11 infants at the end of the week.

A ɥr in supra-atrial leads was seen in 3 infants in Groups I and II initially It persisted in one until the end of the week and was first noted in another at the end of the week, although it may have been present earlier an insufficient number of higher leads being available.

Unlike adults who have either a QS or QR in atrial leads (28), only 7 infants had a QS on the first day of life Those one hour old or less tended to have this pattern in the highest atrial or 1 cm above this lead. This finding persisted in 2 infants at the end of the week. These infants were among the few (12%) who did not have a secondary r wave in supra-atrial leads at the end of the week, even though some had had it earlier

The incidence of deep S waves (not including QS w ves) at any level increases with age i they are present in 31 infants on the first day as compared to 50 of 68 infants t the end of the week.

Although patterns vary significantly at different levels and to some extent on different days during the week, they are sufficiently characteristic to permit recognition of the approximate location of the lead.

Resemblance Between Esophageal and Routine Electrocardiographic Leads

Determination of resemblance of esophageal leads to the other 10 leads (standard bi-polar unipolar and precordial) has been fairly strictly interpreted, requiring P and T waves in the same direction as well as relatively similar amplitudes and ratios of the R and S waves. Therefore, the number of esophageal leads not resembling any other lead is probably greater in this study As there did not appear to be any significant differences, the groups were combined for analysis.

The majority of leads adjacent to the atrium tend not to resemble any lead, while those above the atrium resemble lead aVR more than any other but are seldom identical. In only a few instances does the QRS complex of supra-atrial leads resemble leads I aVL or V_6 little change takes place during the week Scattergrams relating the R/S ratios[1] in lead aVR and supra-atrial lead (a) also suggest a direct linear relationship, especially at the end of the week. During this period little change in the ratio is found in the esophageal lead, but the ratio decreases significantly in lead aVR (i.e a ratio of 2.1 or more is present in .4 infants initially as compared to 8 of 68 infants at the end of the week).

In the lead immediately below the atrium on the first day only 6 of 67 infants have a pattern resembling some other lead, i.e., III, aVF and II in this order At the end of the week, 13 of 66 infants have a pattern resembling either lead aVF or III.

[1] The late R was used determining the ratio in both leads.

In infra-atrial lead (*b*) half of the infants have complexes resembling either lead II or aVF (equal numbers) less than half no lead and 4 either lead III or V_6. At the end of the week, more than 3/4 s of the cases have complexes resembling lead II or aVF less than 1/4 no lead and the remainder leads III and V_6.

In infra-atrial lead (*c*) 2/3 s of the infants have complexes resembling lead II or aVF (but 2/3 s of these are like lead II) less than 1/5th no lead and the rest resemble leads V_6, V_1 and V_4R (in this order). At the end of the week only 8 cases do not resemble either leads II or aVF.

In infra-atrial lead (*d*) on the first day 2/3 s of the cases resemble lead II or aVF (2/3 s lead II). Of the remainder 5 resemble right and 5 left chest leads. At the end of the week 3/4 s of the infants have complexes resembling lead II or aVF (2/3 s lead II) 4 have complexes resembling right and 4 left precordial leads.

In infra-atrial lead (*e*) on the first day ½ of the infants have complexes resembling lead II 1/6th no lead 8 have complexes resembling a right and 6 a left precordial lead, and only a very few leads aVF or III. The distribution is similar at the end of the week.

Scattergrams show a direct linear relationship between amplitudes of *Q*, *R* and *S* waves in infra-atrial leads (*c*) and (*d*) with amplitudes of *Q*, *R* and *S* waves in leads II and aVF on the first and last day of the week.

S–T Junction and Segment

Because of the difficulty in obtaining level baselines, quantitative evaluation of deviation of the *S–T* junction and *T* wave amplitude is not possible. On the *first day* in supra-atrial leads, the *S–T junction* is not displaced in the majority is depressed in most of the others, and elevated in 7 infants (range ±0.05 mV with the exception of 2 cases of 0.1 mV each). In atrial leads there is no deviation in the majority and more often depression in higher and elevation in lower leads with a range of ±0.15 mV in all except one infant (0.2 mV). With more distal passage of the electrode in infra-atrial leads, the range of deviation of the *S–T* junction decreases from ±0.15 mV (maximum 0.2 mV in one infant) to ±0.1 mV (maximum 0.15 mV in one infant).

At the *end of the week* in supra-atrial leads only 2 infants have positive displacement of the *S–T* junction and in all others there is either no deviation or depression of 0.1 mV. In atrial leads, the take-off of the *S–T* junction is displaced in less than 1/3 of the infants, depressed in higher and elevated in lower leads by ±0.25 mV. There are however 3 cases of elevation to 0.3 to 0.35 mV one to as much as 0.8 mV and one of depression to 0.45 mV. In infra-atrial leads, there is no deviation of the *S–T* junction in the majority of infants while most of the others have positive displacement except for 2 infants with negative displacement in distal leads. As had been observed on initial examination, the range decreased from ±0.15 mV (maximum +0.25 mV in one infant) in proximal leads, to ±0.05 mV in more distal leads.

The *S–T segment*[1] often seems somewhat elevated particularly in atrial leads. There

[1] With rapid heart rates the *Tp* wave can cause an apparent depression of the *S–T* segment.

is often a small negative or positive wave following the QRS complex which appears to be a Ta wave, possibly more frequent in atrial and lower infra-atrial leads. Landtman [30] described in premature infants small extra waves following the QRS complex which he attributed to artefacts from muscular activity. It seems unlikely that these waves are artefacts here. In some instances, the segment has a bizarre fall-away contour which arises from a curious relationship to the P wave.

T Wave

On the *first day of life*, T waves are more often positive in distal and negative in proximal leads. As a result, in the lowest infra-atrial leads, only 0 infants have inverted T waves while positive waves are found in 25 infants in infra-atrial lead ( ); 11, 14 and 5 infants in atrial leads (*l*), ( ) and (*h*); 4 and 1 infants in supra-atrial leads (*b*) and (*a*) (the latter measuring 0.03 mV). Infants in Group IV tend t have a greater number of positive T wa es in higher leads than do those in Group I.

At the *end of the week*, the number of positiv deflections increases especially in trial nd high infra-atrial leads and decreases in the lowest infra-atrial lead. However the tendency for T wav di rection *not* to change during this period is statistically significant in most leads (supra-atrial ( ), (*b*), atrial(*h*) ($p < .001$), infra-atrial ( ) (p 03), (*b*), (*c*), (*d*) and ( ) (p 001)).

At *birth*, the amplitude of the T wave ranges from +0.5 mV to −0.3 mV in supra-atrial leads, ±0.45 mV in atrial leads, ±0.5 mV in higher infra-atrial leads and +0.35 mV to −0.1 mV in infra-atrial leads (*d*) and (*e*). At the *end of the week*, amplitude ranges from +0.25 mV to −0.7 mV in supra-atrial leads, +0.8 to −0.35 mV in atrial leads, +0.85 to −0.15 mV in higher infra-atrial leads, and +0.35 to −0.2 mV in lower infra-atrial leads.

The contour of the T wave is often bizarre especially at atrial levels: sometimes wide and coved, or notched, or else with a slurred, ascending or descending limb. (Fig. 4.)

There appears to be direct relationship bet een the amplitude of the T ve in atrial esophageal leads and leads V and V_2, but only on the first day of life.

U Wave

At times, baseline wandering especially in peri-atrial leads, makes it difficult to determine the presence or absence of U waves. But as the incidence in adjacent leads is consistent, the data is presented. All questionable cases were excluded, and, probably for this reason, the majority of infants had no U waves at most levels on the first and last examination. With almost no exception, inverted waves are present in supra-atrial leads and not in infra-atrial leads, and no change occurs during the week. On the other hand, positive waves are seldom seen in supra-atrial leads and are most common in atrial (*s*), (*l*), infra-atrial (*a*) and (*b*) leads with an increase in incidence at the end of the week.

Discussion

From this investigation it is apparent that a fairly regular sequence of esophageal patterns is recorded at different levels but deviations are not uncommon. In-

In infra-atrial lead (*b*) half of the infants have complexes resembling either lead II or aVF (equal numbers) less than half no lead, and 4 either lead III or V_6. At the end of the week, more than 3/4 s of the cases have complexes resembling lead II or aVF less than 1/4 no lead and the remainder leads III and V_6.

In infra-atrial lead (*c*) 2/3 s of the infants have complexes resembling lead II or aVF (but 2/3 s of these are like lead II) less than 1/5th no lead and the rest resemble leads V_6, V_1 and V_4R (in this order). At the end of the week only 6 cases do not resemble either leads II or aVF.

In infra-atrial lead (*d*) on the first day 2/3 s of the cases resemble lead II or aVF (2/3 s lead II). Of the remainder 5 resemble right and 5 left chest leads. At the end of the week 3/4 s of the infants have complexes resembling lead II or aVF (2/3 s lead II). 4 have complexes resembling right and 4 left precordial leads.

In infra-atrial lead (*e*) on the first day ½ of the infants have complexes resembling lead II. 1/6th no lead. 8 have complexes resembling a right and 6 a left precordial lead, and only a very few leads aVF or III. The distribution is similar at the end of the week.

Scattergrams show a direct linear relationship between amplitudes of *Q*, *R* and *S* waves in infra-atrial leads (*c*) and (*d*) with amplitudes of *Q*, *R* and *S* waves in leads II and aVF on the first and last day of the week.

S–T Junction and Segment

Because of the difficulty in obtaining level baselines, quantitative evaluation of deviation of the *S–T* junction and *T* wave amplitude is not possible. On the *first day* in supra-atrial leads, the *S–T junction* is not displaced in the majority. It is depressed in most of the others and elevated in 7 infants (range ± 0.05 mV with the exception of 2 cases of 0.1 mV each). In atrial leads, there is no deviation in the majority and more often depression in higher and elevation in lower leads with a range of ± 0.15 mV in all except one infant (0.2 mV). With more distal passage of the electrode in infra-atrial leads, the range of deviation of the *S–T* junction decreases from ± 0.15 mV (maximum 0.2 mV in one infant) to ± 0.1 mV (maximum 0.15 mV in one infant).

At the *end of the week*, in supra-atrial leads, only 2 infants have positive displacement of the *S–T* junction and in all others there is either no deviation or depression of 0.1 mV. In atrial leads, the take-off of the *S–T* junction is displaced in less than 1/3 of the infants, depressed in higher and elevated in lower leads by ± 0.25 mV. There are however 3 cases of elevation to 0.3 to 0.35 mV, one to as much as 0.8 mV and one of depression to 0.45 mV. In infra-atrial leads there is no deviation of the *S–T* junction in the majority of infants while most of the others have positive displacement except for 2 infants with negative displacement in distal leads. As had been observed on initial examination, the range decreased from ± 0.15 mV (maximum $+0.25$ mV in one infant) in proximal leads, to ± 0.05 mV in more distal leads.

The S–T segment[1] *often seems* somewhat elevated particularly in atrial leads. There

[1] With rapid heart rates the *Tp* wave can cause an apparent depression of the *S–T* segment.

It is therefore of interest that left atrial pressure is not only elevated at birth, but the curve resembles that seen in adults with mitral incompetence. Sodi-Pallares & Calder [43] believe that QS complexes in leads I and aVL may also be due to left atrial dilatation. However P wave duration was not necessarily prolonged in the 9 infants with this pattern in lead I[1] 5 of whom had it on the first day. It was not seen after the age of 53 hours.

The conventionally recorded surface P wave cannot be considered to be an optimal representation of atrial electrocardiographic activity. Moreover the value of esophageal leads in arrhythmias is dependent on considerable amplification of the atrial complex with relatively minor amplification of the ventricular complex. As P waves are small and therefore difficult to measure exactly in conventional leads [11], especially at normal standardization, this selective increase in P wave amplitude in esophageal leads could be put to good advantage if it could be shown to depend on size of or pressure within the left atrium. This might be of special interest in the differential diagnosis of congenital heart disease or the respiratory distress syndrome because roentgenographic evaluation of size of this chamber is difficult at this age [2].

In an attempt to evaluate this, simultaneous recordings of esophageal electrocardiograms and atrial pressure recordings[2] were taken in 6 healthy infants on the first day of life. No relationship was found between P wave amplitude (Rp, Sp, largest intrinsic deflection, largest negative and positive P waves) in esophageal leads and mean atrial pressure in either the left or the right atrial chamber, but the group is too small for any definite conclusion. The results of other studies relating P wave amplitude to atrial size and pressure are also conflicting. Gordon *et al.* [24], using heart specimens, found a negative correlation between P wave amplitude and left atrial volume—that is, the lower the P wave amplitude the greater the left atrial volume; while both Escobar *et al.* [21] and Testelli [46] were unable to find a relation between height of P waves in the left atrium and the left atrial pressure. Dodge & Sandler [20] also found a poor relation between left atrial volume, measured on biplane angiocardiograms, and left atrial pressure. However these findings in adults may not be applicable to newborn infants.

However, a number of investigations have described changes in the esophageal electrocardiogram in patients with left atrial enlargement of different etiology. According to Conte & Fusaro [14], the following criteria constitute *definite* evidence of left atrial enlargement: 1) increased area of recording of atrial leads (also noted by Benoit & Rodriguez Alvarez [6]), 2) increased amplitude of the Rp wave [23, 37] and 3) increased ratio of the P–R_{II}/iQ intervals [53]. Less certain evidence of left atrial enlargement is furnished by the following: 1) increased amplitude of the Sp wave [13] and 2) increased duration of DI (= Q–Rp interval

[1] One infant also had QS in aVL.

[2] Cardiac catheterization performed by Dr H. Arcilla.

[3] The size of the left atrium also does not appear to be related to the mean electrical axis of the P [47].

[4] P–R_{II}/iQ interval: ratio of P–R interval in lead II to interval from onset of atrial intrinsic deflection (i) to ventricular esophageal Q wave.

sertion of the electrode to a specific distance from the nares *is not satisfactory* because as discussed earlier levels vary directly with length. *Instead the* location of the transitional complex of the P wave should first be *determined* According to Frau [23] this corresponds to the distance (cm) measured from the superior portion of the cricoid cartilage to the base of the xyphoid process multiplied by the coefficient 1 33 (Lewis rule) As significant alterations in complexes occur with minimal displacement of the electrode *recordings* should be taken at 1/2 cm intervals *over* a distance of at least 5 cm above and below this point. Multiple simultaneous bipolar leads are probably preferable

In newborns with late clamping of the umbilical cord atrial pressures are elevated during the first hour of life and left atrial pressure curves show prominent *v* waves [8 10] According to the former authors [8] this may be the result of low distensibility characteristics of the left heart chambers particularly of *the left atrium and to failure of* this chamber to effectively dilate immediately following the increase in pulmonary blood flow after birth This region may be comparatively blind on conventional electrocardiography but the esophagus is a convenient and safe route for obtaining semi-direct leads of the left atrium without resorting to more complex procedures such as intracardiac catheterization Study of the posterior aspect of the heart is important in the newborn because during the transition from fetal to neonatal existence increase in the pulmonary circulation and presence of a left-to-right shunt through the ductus arteriosus must necessarily place an increased load on the left heart.

There is suggestive evidence that the routine electrocardiogram reflects some of the changes associated with hemodynamic adaptation to extrauterine life and *it does* not seem unreasonable to *suppose that* some of these changes should also be noted on the esophageal electrocardiogram For example, a particular *pattern of* change is seen in infants with late *clamping of the* umbilical cord, especially on the first day of life. At birth most electrocardiographic intervals (P wave duration P–R interval QRS interval Q–Tc interval) are prolonged and amplitude of R waves over the right and S waves over the left chest is increased. After the first hour of life the mean T vector shifts to the right and anteriorly [25 51] The genesis of some of these findings has been ascribed to initial systolic overload of the right ventricle followed by transient physiologic overload of the left ventricle. These changes accompany decrease in pulmonary vascular resistance after lung inflation, increase in systemic resistance with cessation of placental circulation and reversal of flow through the ductus arteriosus.

Statistically significant changes in duration of intervals and voltage of deflections on the esophageal electrocardiogram have been shown to occur during the first week of life Some of these parallel previously reported *changes in routine* leads—e.g prolongation of P wave duration, especially during the first 35 to 60 minutes of life while others do not—e.g lower amplitude P waves in infants one hour of age or less. Widened P waves indicate left atrial enlargement, and

it is therefore of interest that left atrial pressure is not only elevated at birth, but the curve resembles that seen in adults with mitral incompetence. Sodi-Pallares & Calder [43] believe that QS complexes in leads I and aVL may also be due to left atrial dilatation. However P wave duration was not necessarily prolonged in the 9 infants with this pattern in lead I,[1] 5 of whom had it on the first day. It was not seen after the age of 53 hours.

The conventionally recorded surface P wave cannot be considered to be an optimal representation of atrial electrocardiographic activity. Moreover the value of esophageal leads in arrhythmias is dependent on considerable amplification of the atrial complex with relatively minor amplification of the ventricular complex. As P waves are small and therefore difficult to measure exactly in conventional leads [11], especially at normal standardization, this selective increase in P wave amplitude in esophageal leads could be put to good advantage if it could be shown to depend on size of, or pressure within the left atrium. This might be of special interest in the differential diagnosis of congenital heart disease or the respiratory distress syndrome because roentgenographic evaluation of size of this chamber is difficult at this age [2].

In an attempt to evaluate this, simultaneous recordings of esophageal electrocardiograms and atrial pressure recordings[2] were taken in 6 healthy infants on the first day of life. No relationship was found between P wave amplitude (Rp, Sp, largest intrinsic deflection, largest negative and positive P waves) in esophageal leads and mean atrial pressure in either the left or the right atrial chamber but the group is too small for any definite conclusion. The results of other studies relating P wave amplitude to atrial size and pressure are also conflicting. Gordon *et al.* [24], using heart specimens, found a negative correlation between P wave amplitude and left atrial volume—that is, the lower the P wave amplitude the greater the left atrial volume; while both Escobar *et al.* [21] and Testelli [46] were unable to find a relation between height of P waves in the left atrium and the left atrial pressure. Dodge & Sandler [20] also found a poor relation between left atrial volume, measured on biplane angiocardiograms, and left atrial pressure.[3] However these findings in adults may not be applicable to newborn infants.

However a number of investigations have described changes in the esophageal electrocardiogram in patients with left atrial enlargement of different etiology. According to Conte & Fusaro [14], the following criteria constitute *definite* evidence of left atrial enlargement: 1) increased area of recording of atrial leads (also noted by Benot & Rodriguez Alvarez [9]), 2) increased amplitude of the Rp wave [23, 37] and 3) increased ratio of the P R_{pi}/Q interval[4] [33]. Less certain evidence of left atrial enlargement is furnished by the following: 1) increased amplitude of the Sp wave [12] and 2) increased duration of DI ($-Q-Rp$ inter

[1] One infant also had QS in aVL.

sertion of the electrode to a specific distance from the nares is not satisfactory because as discussed earlier levels vary directly with length Instead the location of the transitional complex of the P wave should first be determined. According to Frau [23] this corresponds to the distance (cm) measured from the superior portion of the cricoid cartilage to the base of the xyphoid process multiplied by the coefficient 1 33 (Lewis rule) As significant alterations in complexes occur with minimal displacement of the electrode recordings should be taken at 1/2 cm intervals over a distance of at least 5 cm above and below this point. Multiple simultaneous bipolar leads are probably preferable

In newborns with late clamping of the umbilical cord atrial pressures are elevated during the first hour of life and left atrial pressure curves show prominent v waves [8 10] According to the former authors [8] this may be the result of low distensibility characteristics of the left heart chambers, particularly of the left atrium and to failure of this chamber to effectively dilate immediately following the increase in pulmonary blood flow after birth This region may be comparatively blind on conventional electrocardiography but the esophagus is a convenient and safe route for obtaining semi-direct leads of the left atrium without resorting to more complex procedures such as intracardiac catheterization Study of the posterior aspect of the heart is important in the newborn because during the transition from fetal to neonatal existence, increase in the pulmonary circulation and presence of a left-to-right shunt through the ductus arteriosus must necessarily place an increased load on the left heart.

There is suggestive evidence that the routine electrocardiogram reflects some of the changes associated with hemodynamic adaptation to extrauterine life and it does not seem unreasonable to suppose that some of these changes should also be noted on the esophageal electrocardiogram. For example a particular pattern of change is seen in infants with late clamping of the umbilical cord, especially on the first day of life At birth most electrocardiographic intervals (P wave duration P–R interval QRS interval Q–Tc interval) are prolonged and amplitude of R waves over the right and S waves over the left chest is increased After the first hour of life the mean T vector shifts to the right and anteriorly [25 51] The genesis of some of these findings has been ascribed to initial systolic overload of the right ventricle followed by transient physiologic overload of the left ventricle These changes accompany decrease in pulmonary vascular resistance after lung inflation, increase in systemic resistance with cessation of placental circulation and reversal of flow through the ductus arteriosus.

Statistically significant changes in duration of intervals and voltage of deflections on the esophageal electrocardiogram have been shown to occur during the first week of life Some of these parallel previously reported changes in routine leads—e g , prolongation of P wave duration, especially during the first 35 to 60 minutes of life while others do not—e g lower amplitude P waves in infants one hour of age or less. Widened P waves indicate left atrial enlargement and

it is therefore of interest that left atrial pressure is not only elevated at birth, but the curve resembles that seen in adults with mitral incompetence Sodi-Pallares & Calder [43] believe that QS complexes in leads I and aVL may also be due to left atrial dilatation. However P wave duration was not necessarily prolonged in the 9 infants with this pattern in lead I [1] 5 of whom had it on the first day It was not seen after the age of 53 hours.

The conventionally-recorded surface P wave cannot be considered to be an optimal representation of atrial electrocardiographic activity Moreover the value of esophageal leads in arrhythmias is dependent on considerable amplification of the atrial complex with relatively minor amplification of the ventricular complex. As P waves are small and therefore difficult to measure exactly in conventional leads [11], especially at normal standardization, this selective increase in P wave amplitude in esophageal leads could be put to good advantage if it could be shown to depend on size of, or pressure within the left atrium This might be of special interest in the differential diagnosis of congenital heart disease or the respiratory distress syndrome because roentgenographic evaluation of size of this chamber is difficult at this age [2]

In an attempt to evaluate this, simultaneous recordings of esophageal electrocardiograms and atrial pressure recordings[2] were taken in 6 healthy infants on the first day of life No relationship was found between P wave amplitude (R_p, S_p largest intrinsic deflection, largest negative and positive P waves) in esophageal leads and mean atrial pressure in either the left or the right atrial chamber but the group is too small for any definite conclusion. The results of other studies relating P wave amplitude to atrial size and pressure are also conflicting. Gordon *et al.* [4] using heart specimens, found a negative correlation between P wave amplitude and left atrial volume—that is, the lower the P wave amplitude the greater the left atrial volume while both Escobar *et al.* [*1] and Testelli [46] were unable to find a relation between height of P waves in the left atrium and the left atrial pressure. Dodge & Sauter [20] also found a poor relation between left atrial volume measured on biplane angiocardiograms, and left atrial pressure [3] However these findings in adults may not be applicable to newborn infants.

However a number of investigations have described changes in the esophageal electrocardiogram in patients with left atrial enlargement of different etiology According to Conte & Fusaro [14], the following criteria constitute *definite* evidence of left atrial enlargement. 1) Increased area of recording of atrial leads (also noted by Benot & Rodriguez Alvarez [6]) 2) increased amplitude of the R_p wave [23, 37] and 3) increased ratio of the P–R_{II}/iQ intervals[4] [53]. Less certain evidence of left atrial enlargement is furnished by the following: 1) increased amplitude of the S_p wave [13] and 2) increased duration of DI (=Q–R_p inter

[1] One infant also had QS in VL.

[2] Cardiac catheterization performed by Dr B Arcilla.

[3] The volume of the left atrium also does not appear to be related to the mean electrical axis of the P wave [47]

[4] P–R_{II}/iQ interval ratio of P R interval in lead II to interval from onset of atrial intrinsic deflection ( ) ventricular esophageal Q wave.

val) Bengtsson studying the esophageal electrocardiogram in 20 healthy children and 32 with congenital heart disease concluded that left atrial hypertrophy was generally accompanied by an increase in P wave amplitude and/or prolongation of the Q–Rp time Similar findings have been reported by Frau Wenger & Hofmann Credner and Franke

In this investigation—1) the area of recording of atrial leads is the same in both groups of infants on the first day of life and increases at the end of the week, 2) the amplitude of the Rp wave in atrial leads is lower than in adults, and 3) the ratio of the P–R_{II}/tQ intervals was not determined. However the Q–Rp time was prolonged and although the amplitude of the Sp wave was significantly lower in infants less than one hour of age the values during the week exceed those reported in children and adults Thus only their less certain criteria for left atrial enlargement are fulfilled

A relatively low amplitude Sp wave would result from either a decrease in magnitude and/or a change in direction of the mean P wave vector It does not seem to be an artefact because the same trend is seen at more than one level and the amplitude increases in younger and decreases in older infants at the end of the week An increased amount of air in the esophagus might reduce voltage although it seems more likely that older infants would have swallowed more air The distance of an electrode from the heart and the degree of pulmonary inflation are important factors influencing the P wave especially in chest leads but as the esophageal electrode lies in almost direct contiguity with the left atrium such explanations seem untenable.

On the other hand high systolic pressure in the right ventricle and low pO of the arterial blood, which are generally present after birth are usually said to be associated with an increase in amplitude of the P wave Similarly stretching of the atria an expected result of late clamping of the umbilical cord, also increases potential, either directly or by sympathetic stimulation [31] However the effects of transient atrial overload must depend not only on the size of the placental transfusion which may amount to 1/4th the total blood volume but also on which chamber is affected more. As the vector tends to shift anteriorly with right atrial enlargement and posteriorly with left atrial enlargement differentiation should be possible Recent analysis of atrial vectorcardiographic patterns accords with this view but considerable overlap is present and those authors were unable to distinguish between systolic overload (increased pressure) and diastolic overload (increased flow) [41]

Rothberger & Winterberg [39] have experimentally demonstrated that increased vagal tone decreases P wave amplitude and there is both clinical and experimental evidence that hyperpotassemia is also associated with a decrease in P wave amplitude [45 52] But the factors controlling P wave contour and amplitude are multiple and poorly understood. As Berliner & Master [7] point out no constant relation between height of P wave and degree of atrial enlargement can be expected, just as there is no constant relation between height of QRS complex and degree of ventricular enlargement However a failing heart often shows a

low voltage ventricular complex. Similarly voltage of the atrial wave must also be influenced by variations in functional status of atrial musculature. It is, therefore, not surprising that marked atrial hypertrophy is often associated with a P wave of normal amplitude.

In adults, a Q wave in infra-atrial leads which equals or exceeds 0.4 mV or 25% of the R wave in the same lead is considered suggestive of myocardial infarction [35]. However several healthy adults studied by Kistin *et al.* [28] as well as 3 infants in this series had Q waves which were abnormal by these criteria. As neither group nor individual differences in mean electrical axis were found during the first week of life, this parameter cannot account for the significant changes in amplitude of the ventricular QRS complex.

Although the incidence of arrhythmias is low in this age group the technique is well tolerated if gently carried out,[1] and it should be used in all complex cases. Whether the esophageal electrocardiogram in newborns is of value in early diagnosis of conditions primarily placing a load on the left heart still remains to be determined. The establishment of these normal standards based on a carefully selected group of healthy infants will, it is hoped, provide a sound basis for future studies.

Conclusion

Normal standards of the esophageal electrocardiogram were determined in 100 healthy infants of normal birth weight (full-term) who fulfilled the following criteria.) uncomplicated singleton delivery b) cephalic presentation, c) late clamping of the umbilical cord d) no maternal analgesia or anesthesia, and e) no known maternal illness.

These infants were serially examined—immediately after birth on the second, third and fifth or sixth days of life—and the following parameters were correlated. a) 21 to 31 gastric and esophageal leads, b) blood pressure (using xylol indicator), c) heart volume (determined on roentgenograms of the chest on the first and last examination) d) 16-lead electrocardiogram, e) phonocardiogram f) physical findings, g) age weight and length.

Statistical analysis of the data showed that multiple changes occur particularly on the first day of life, but also at the end of the week. These changes primarily affect P wave duration, and amplitude of the P wave and QRS complex. Moreover a number of relationships were found between some of the above-listed parameters.

As this is the only study of the esophageal electrocardiogram in newborns, the above-described control series of infants is considered essential for further critical evaluation of these leads. The results to date justify extension of studies—in particular to infants with circulatory problems placing a load on the left heart.

Acknowledgement

Dr John Lind, Professor and Chairman of the Department of Pediatrics, Karolinska Hospital, and Dr Charles E. Kossmann, Professor of Medicine New York University Medical Center read the manuscript and gave helpful advice. The careful technical assistance of Mrs. Siv Lundqvist is gratefully acknowledged

[1] Continuous recordings were taken in some infants during passage of the electrode. Apart from slight increase in heart rate, only an occasional premature atrial beat or slight shift in pacemaker was observed.

val) Bengtsson studying the esophageal electrocardiogram in 20 healthy children and 32 with congenital heart disease concluded that left atrial hypertrophy was generally accompanied by an increase in P wave amplitude and/or prolongation of the Q–Rp time Similar findings have been reported by Frau Wenger & Hofmann Credner and Franke

In this investigation—1) the area of recording of atrial leads is the same in both groups of infants on the first day of life and increases at the end of the week, 2) the amplitude of the Rp wave in atrial leads is lower than in adults; and 3) the ratio of the P–R_{II}/tQ intervals was not determined. However the Q–Rp time was prolonged and although the amplitude of the Sp wave was significantly lower in infants less than one hour of age the values during the week exceed those reported in children and adults Thus only their less certain criteria for left atrial enlargement are fulfilled.

A relatively low amplitude Sp wave would result from either a decrease in magnitude and/or a change in direction of the mean P wave vector It does not seem to be an artefact because the same trend is seen at more than one level and the amplitude increases in younger and decreases in older infants at the end of the week An increased amount of air in the esophagus might reduce voltage although it seems more likely that older infants would have swallowed more air The distance of an electrode from the heart and the degree of pulmonary inflation are important factors influencing the P wave especially in chest leads but as the esophageal electrode lies in almost direct contiguity with the left atrium such explanations seem untenable

On the other hand, high systolic pressure in the right ventricle and low pO of the arterial blood, which are generally present after birth, are usually said to be associated with an increase in amplitude of the P wave Similarly stretching of the atria an expected result of late clamping of the umbilical cord also increases potential either directly or by sympathetic stimulation [31] However the effects of transient atrial overload must depend not only on the size of the placental transfusion, which may amount to 1/4th the total blood volume but also on which chamber is affected more As the vector tends to shift anteriorly with right atrial enlargement and posteriorly with left atrial enlargement differentiation should be possible Recent analysis of atrial vectorcardiographic patterns accords with this view but considerable overlap is present, and these authors were unable to distinguish between systolic overload (increased pressure) and diastolic overload (increased flow) [41]

Rothberger & Winterberg [39] have experimentally demonstrated that increased vagal tone decreases P wave amplitude and there is both clinical and experimental evidence that hyperpotassemia is also associated with a decrease in P wave amplitude [45 5?] But the factors controlling P wave contour and amplitude are multiple and poorly understood. As Berliner & Master [7] point out no constant relation between height of P wave and degree of atrial enlargement can be expected, just as there is no constant relation between height of QRS complex and degree of ventricular enlargement However a failing heart often shows a

CONSTANTIN CHOREMIS

(1898–1966)

The child is born from his mother womb, but it is in her embrace that he becomes human being.

Professor Constantin Choremis was born in 1898 in the mountain village of Khmenti west of Corinth. He died quite unexpectedly at the age of 68.

Choremis graduated from the Medical School of Athens University in 1921 and then went to Germany for postgraduate studies. There he worked for three years under Professor Czerny in Berlin. He was elected to the chair of Pediatrics at Athens University in 1935. In 1956–57 he served as Rector of the University and in 1957 he was elected member of the Academy of Athens. In 1959 he became President of the National Supreme Health Council.

Professor Choremis was a member of many European pediatric societies and an honorary member of British and American pediatric societies as well. He was well-known internationally having participated in a large number of international pediatric congresses.

Choremis devoted his life to the welfare of children. Throughout his career as a physician and as a university professor in all his speeches, scientific publications, and daily activities, he manifested in many ways his love and affection for his small charges.

Professor Choremis interests covered almost the whole of pediatrics: growth, blood disorders, tuberculosis, nutrition, contagious and collagen diseases, and genetics—all were subjects of investigation in the University Pediatric Clinic.

Choremis became interested in tuberculosis at the beginning of his career and kept up that interest throughout his professional life. While still in Berlin, he published a monograph on the subject which won the praise of his teacher Professor Czerny.

During the war and the German occupation, Professor Choremis concentrated on the study of the growth and general health of Athens-area children from birth to puberty. The results of this investigation, which was interrupted when Professor Choremis was imprisoned by the German authorities, were presented at the 5th International Congress of Pediatrics in New York in 1948 and gave rise to enthusiastic comments. Professor Choremis study and conclusions were widely discussed internationally and helped greatly to bring about an increase in the daily rations offered through foreign aid to the war-stricken and deprived Greek children.

After the war Professor Choremis turned again to the study of childhood tuberculosis. He and his collaborators published a total of 63 papers on this subject. A significant contribution of his was his research on the application of streptomycin in the treatment of tuberculous meningitis. His monograph on

CONSTANTIN CHOREMIS

(1898–1966)

The child is born from his mother's womb, but it is in her embrace that he becomes a human being.

Professor Constantin Choremis was born in 1898 in the mountain village of Klimenti west of Corinth. He died quite unexpectedly at the age of 68.

Choremis graduated from the Medical School of Athens University in 1921 and then went to Germany for postgraduate studies. There he worked for three years under Professor Czerny in Berlin. He was elected to the chair of Pediatrics at Athens University in 1935. In 1956–57 he served as Rector of the University and in 1957 he was elected member of the Academy of Athens. In 1960 he became President of the National Supreme Health Council.

Professor Choremis was a member of many European pediatric societies and an honorary member of British and American pediatric societies as well. He was well known internationally having participated in a large number of international pediatric congresses.

Choremis devoted his life to the welfare of children. Throughout his career as physician and as a university professor in all his speeches, scientific publications, and daily activities, he manifested in many ways his love and affection for his small charges.

Professor Choremis' interests covered almost the whole of pediatrics: growth, blood disorders, tuberculosis, nutrition, contagious and collagen diseases, and genetics—all were subjects of investigation in the University Pediatric Clinic.

Choremis became interested in tuberculosis at the beginning of his career and kept up that interest throughout his professional life. While still in Berlin, he published a monograph on the subject which won the praise of his teacher Professor Czerny.

During the war and the German occupation, Professor Choremis concentrated on the study of the growth and general health of Athens-area children from birth to puberty. The results of this investigation, which was interrupted when Professor Choremis was imprisoned by the German authorities, were presented at the 5th International Congress of Pediatrics in New York in 1946 and gave rise to enthusiastic comments. Professor Choremis' study and conclusions were widely discussed internationally and helped greatly to bring about an increase in the daily rations offered through foreign aid to the war-stricken and deprived Greek children.

After the war Professor Choremis turned again to the study of childhood tuberculosis. He and his collaborators published a total of 63 papers on this subject. A significant contribution of his was his research on the application of streptomycin in the treatment of tuberculous meningitis. His monograph on

titled "The Results of Streptomycin Therapy in Childhood Tuberculosis" was singled out for praise by the Academy of Athens in 1948 and its author was presented with a special award.

Choremis discovered that tuberculous bacilli were often present in the CSF the bone-marrow and the liver of children with common uncomplicated primary pulmonary tuberculosis, thus proving that even in this simple form of the disease tuberculous bacilli were not confined to the lung but that bacteremia is rather common. Another important discovery was that of the bacteriophage of tuberculosis. Professor Waksman commented on the "marvelous work of the Pediatric Clinic of Athens University" when he received the Nobel Prize Award.

Professor Choremis work on hematological problems is also well known. He discovered the first focus of the sickle cell trait in Greece thus proving that it is not rare among Caucasians. During recent years he and his team studied the complications of glucose-6-phosphate dehydrogenase deficiency (favism neonatal jaundice etc.) as well as the geographical distribution of this enzyme deficiency in Greece and its relation to the hemoglobinopathies and malaria. He was invited to participate in a meeting of a WHO scientific group of nine experts on Hemoglobinopathies and Allied Disorders that was held in Genova from the 14th to the 10th of December 1965 He was elected Vice-Chairman of this meeting which reviewed the present state of knowledge on hemoglobinopathies and allied disorders, especially that of G-6-PD deficiency and prepared a report for the Director General.

The discovery of the excretion of var lactic acid in the urine of patients wi rheumatic fever was the latest achievment of the Research Laboratory under h direction. In his lifetime he published mo than 250 scientific papers three mon graphs, and a textbook of Pediatrics.

Professor Choremis was not only out standing as a scientist a scholar and teacher at the same time he was a grea personality with a strong influence on hi pupils. He was attracted not by petty casuistic matters but by the great prob lems in pediatrics. Although he was an eloquent speaker with more than 30 years experience in university lecturing, he always took pains to prepare his lectures. He had a real flair for beautiful but always correctly selected words with which he expressed his original, stimula ting, and inspiring ideas. His style was brilliant and his lectures deeply impressed his audiences.

In his clinical rounds he used to give us examples of sound clinical observation, and forced us to be critical and to avoid logical errors in our conclusi n He was an indefatigable worker and fanatic in the pursuit of solutions t problems. Although he was a superl her and an outstanding researcher njoyed his work in those two ca what he gave the greatest impo to was the welfare of each patient f his most facile expressions of th was uttered in a speech in Septem 1 964 when he pleaded with his aud decade in what way we can c perit so that we can forge a universal hold to hold over the child for his prot n

His radiating pers nality his simpl and straightforward hara ter his good

will and kind understanding and tolerance of minor human weaknesses easily won the affection of the people with whom he came in contact. He put his heart and soul into whatever he did. He worked extremely hard all his life, giving of himself without stint and in the end died in harness, leaving us much earlier than anyone expected.

There are some deaths which we mourn, but which we are able to accept as a natural end to life; there are other deaths, however which we feel are a cruel injustice. This is the feeling of all those who had come into personal contact with him, and this is especially true of his collaborators and pupils.

It was not merely those who had the good fortune to work closely with him who loved him The warm glow of his personality was such that anyone who had even the slightest share in his professional and research work would go to any length to help him. Choremis was not merely a brilliant scholar and scientist. He was above all a man of thought. His philosophical soul surveyed mankind from a high vantage point. This is why he imbued his clinic with a special atmosphere characterized not only by a searching after scientific truths, but also by high ideals and humanity None of those who worked with him can forget this atmosphere, which will continue to inspire them and enable them to carry on his work

N Matsaniotis, M.D
Athens, Greece

titled "The Results of Streptomycin Therapy in Childhood Tuberculosis" was singled out for praise by the Academy of Athens in 1948 and its author was presented with a special award.

Choremis discovered that tuberculous bacilli were often present in the CSF the bone-marrow and the liver of children with common uncomplicated primary pulmonary tuberculosis, thus proving that even in this simple form of the disease tuberculous bacilli were not confined to the lung but that bacteremia is rather common. Another important discovery was that of the bacteriophage of tuberculosis. Professor Waksman commented on the marvelous work of the Pediatric Clinic of Athens University when he received the Nobel Prize Award.

Professor Choremis work on hematological problems is also well known. He discovered the first focus of the sickle cell trait in Greece thus proving that it is not rare among Caucasians. During recent years he and his team studied the complications of glucose-6-phosphate dehydrogenase deficiency (favism neonatal jaundice etc) as well as the geographical distribution of this enzyme deficiency in Greece and its relation to the hemoglobinopathies and malaria. He was invited to participate in a meeting of a WHO scientific group of nine experts on Hemoglobinopathies and Allied Disorders that was held in Geneva from the 14th to the 10th of December 1965 He was elected Vice-Chairman of this meeting which reviewed the present state of knowledge on hemoglobinopathies and allied disorders especially that of G 6-PD deficiency and prepared a report for the Director General

The discovery of the excretion of vanil lactic acid in the urine of patients with rheumatic fever was the latest achievement of the Research Laboratory under his direction. In his lifetime he published more than 250 scientific papers, three monographs, and a textbook of Pediatrics.

Professor Choremis was not only outstanding as a scientist, a scholar and a teacher at the same time he was a great personality with a strong influence on his pupils. He was attracted not by petty casuistic matters, but by the great problems in pediatrics. Although he was an eloquent speaker with more than 30 years experience in university lecturing he always took pains to prepare his lectures. He had a real flair for beautiful but always correctly selected words with which he expressed his original stimulating, and inspiring ideas. His style was brilliant and his lectures deeply impressed his audiences.

In his clinical rounds, he used to give us examples of sound clinical observation and forced us to be critical and to avoid logical errors in our conclusions. He was an indefatigable worker and a fanatic in the pursuit of solutions to his problems. Although he was a superb teacher and an outstanding researcher and enjoyed his work in these two capacities what he gave the greatest importance to was the welfare of each patient. One of his most facile expressions of this belief was uttered in a speech in September 1964 when he pleaded with his audience to decide in what way we can cooperate so that we can forge a universal shield to hold over the child for his protection

His radiating personality his simple and straightforward character his good

will and kind understanding and tolerance of minor human weaknesses easily won the affection of the people with whom he came in contact. He put his heart and soul into whatever he did. He worked extremely hard all his life giving of himself without stint, and in the end died in harness, leaving us much earlier than anyone expected.

There are some deaths which we mourn, but which we are able to accept as a natural end to life; there are other deaths, however which we feel are a cruel injustice. This is the feeling of all those who had come into personal contact with him, and this is especially true of his collaborators and pupils.

It was not merely those who had the good fortune to work closely with him who loved him. The warm glow of his personality was such that anyone who had even the slightest share in his professional and research work would go to any length to help him. Choremis was not merely a brilliant scholar and scientist. He was above all a man of thought. His philosophical soul surveyed mankind from a high vantage point. This is why he imbued his clinic with a special atmosphere characterized not only by a searching after scientific truths, but also by high ideals and humanity. None of those who worked with him can forget this atmosphere which will continue to inspire them and enable them to carry on his work

Recurrent Disorders in Children A Synthesis

by JOHN APLEY

Many childhood disorders come and go, only to return. Heberden [6] mentioned pains which are regularly intermittent and Samuel Gee [5] described "fitful or recurrent vomiting" But only in 1903 did Wyllie & Schlesinger [10] give a unified account of recurrent abdominal pains and vomiting with fever and headache, under the title "The periodic group of disorders in childhood and to their tetrad should now be added a fifth, diurnal limb pains [3], Mac Keith & O'Neill [7], Apley [2] and others, have emphasised that such recurrent bodily symptoms are commonly associated with emotional disturbances. A synthesis that includes both physical and emotional factors will be attempted in the discussion that follows.

As a general descriptive term I prefer *recurrent* (to course or run, again) rather than rhythmical or *periodic* (by which a regularity of intervals is understood) or cyclic (by which a constant order of events is implied). In the common syndromes of childhood a regular periodicity is not characteristic and the order of events may change So also may the components of the syndrome change the vomiting infant may become the little belly-acher in childhood and develop migraine in adult life [2].

Order is Heav'n's first law" wrote Alexander Pope the poet, and, in the quest for order the founders of western medicine tried to discern rhythms in disease. The word lunatic is a reminder that disease *rhythms* have been linked with phases of the moon. They have been linked also with mystical numbers, in the Middle Ages 7 was referred to as the Medical Number and we still hear mothers say 'He will grow out of it when he is 7 or 14 or 21 years old. Since the early days of medicine more convincing explanations for some disease rhythms have been established. In malaria the rhythm reflects the life history of the plasmodium, but such regular rhythms as that of the fever in Hodgkin's disease, in brucellosis, and occasionally in *rheumatoid* arthritis, are unexplained.

Descriptions, like that by Osler of a woman with periodic oedema recurring at intervals of 4 to 6 weeks for 74 years, linger in the memory but in practice a regular *rhythm*, a true periodicity is very uncommon. Some so-called regular rhythms are in fact irregular and many are imagined, the attempt to establish heaven's first law often goes further than the evidence warrants. For some years I have gone carefully into detail whenever

recurrent aches in the limbs and was *stunted in growth*. When eventually pseudohypoparathyroidism was diagnosed, and she was given calcium, the behaviour disorders, like the fits and pains, cleared up.

The inter-relationship of body and mind. In some of the above examples it may reasonably be held that a primary bodily disturbance was associated with emotional changes. We may recall also that influenza can be followed by depression, and that the sub-thyroid child is slow physically, mentally and emotionally. Recurrent manifestations of the epilepsies may take the form not only of fits, but also of behavioural, emotional, and occasionally somatic, disturbances; though in the epilepsies an underlying organic disorder is usually presumed, the recurrences are frequently provoked or increased by emotional stress. I summarise the history of a boy in whom severe recurrent disturbances, in the last of which he died, appeared to be provoked indiscriminately either by physical or emotional stress.

S. W. had 6 similar attacks between the ages of 13 and 35 months. In each he became irritable, listless and drowsy or comatose. He vomited, was feverish and became dehydrated; hyperglycaemia, ketosis and acidosis developed. In the last two attacks he was ataxic. On each occasion a characteristic smell was observed, eventually identified as that of butyric acid. At autopsy the only abnormality found was gliosis of the white matter including the cerebellum and brain-stem, which was considered to be a secondary phenomenon, a response to a generalised metabolic disorder. (Dr. R. P. Norman.)

The study of widespread bodily disturbances in the recurrent disorders is important in their own right, of course, but also because emotional stresses effect changes in the body largely through the endocrine and autonomic systems.

Primary emotional factors. I was long puzzled by the recurrence of episodes of severe thyrotoxicosis in a girl, until the family doctor remarked that they occurred whenever her father came home from *prison on probation!* Retention of sodium and water during periods of emotional tension, followed by a diuresis after relaxation of the tension, has been reported [8]. Again, it is recognised that exacerbation of diabetes mellitus may be provoked by emotional disturbances, which themselves may be recurrent. In such cases measurable biochemical disturbances may be demonstrated, but they are secondary to emotional disturbance.

Housman, the poet who so effectively combined lyricism and stoicism, made an interesting observation. If certain lines of poetry came into his mind while he was shaving, the hair on his face bristled so stiffly that the razor would cut them only with difficulty. We do not need the poet's piercing eye to observe many commoner examples of bodily reactions occurring with emotional stress. Blushing with embarrassment is one example, and "getting hot under the collar" with rage is another. Such everyday somatic reactions to emotions are normal; when they are excessive they may be termed psychosomatic disorders.

A large proportion of the recurrent disorders of children fulfil the criteria of psychosomatic disorder: no organic cause can be demonstrated, and there is positive evidence of an emotional disturbance, while symptoms may occur in an evident time relationship with periods of emotional stress.

I am told by his mother that Johnny's whatever-it-is comes on every month, exactly to the day and I am getting used to being disappointed.

But the important concept of recurrence remains valid for another reason—that in many instances *a pattern of disorder* can be recognised.

The Significance of Recurrence

Medicine is moving away from a pre-occupation with acute disease a preoccupation which encouraged the notion that disease is an entity a thing apart from the patient. Illness may be an aspect of living not an isolated episode with a clear beginning and end" With this approach, and with a better appreciation that symptoms and signs are reactions (sometimes maladaptive) to external or to internal stress, we are beginning to perceive some order in many of the recurrent disorders. When a pattern of illness keeps recurring we become less willing to accept it as an isolated episode and the recurrence as a series of flukes we seek to identify underlying factors which help to explain them In each individual, until the hypothesis is disproved *we should consider recurrent disorders as the intermittent expressions of persistent disorder*

The search for cause and effect may be philosophically unfashionable nowadays, but it is very useful in medical practice Though for simplicity I separate causes into internal and external groups, it should be emphasised that the two groups are often inseparable and the factors are frequently multiple Man, in health or in disease is a complex of interlocking and integrated mechanisms if we take him apart to look at them, we must remember to put him together again.

Internal factors

Primary organic factors in recurrent disorders An obvious example is recurrent urinary infection, in which an underlying *congenital* malformation of the kidney can often be demonstrated. Another is recurrent dislocation of the shoulder in which an anatomical defect (which may have been caused in the first place by injury) can be found in nearly every case

These examples are obvious because the expression of disorder is localised, when it is *not* localised a persistent underlying disorder is *more likely* to escape notice. Recurrent non localised infections are occasionally associated with a deficiency of gammaglobulin, but, as an *illustration* of the multiplicity of factors often involved, recurrent infections are much more commonly associated with poverty malnutrition or over-crowding

Order among disorder is likely to escape notice if the manifest disturbances vary from time to time. An example is polyarteritis nodosa, with recurrent but protean manifestations such as colic fever asthma anaemia neuritis. Other examples are acute porphyria with its variable episodes of paralysis, colicky pain or hysteria and gout with its somatic and emotional changes.

Such metabolic disorders are of particular interest because of the varying display of both bodily and emotional disturbances. I mention as another example a child, whose predominant disturbance had been considered to be one of behaviour though there was also a history of occasional fits and she suffered from

recurrent aches in the limbs and was stunted in growth. When eventually pseudohypoparathyroidism was diagnosed, and she was given calcium, the behaviour disorders, like the fits and pains, cleared up.

But the important concept of recurrence remains valid for another reason—that in many instances *a pattern of disorder* can be recognised.

The Significance of Recurrence

Medicine is moving away from a preoccupation with acute disease a preoccupation which encouraged the notion that disease is an entity a thing apart from the patient. Illness may be an aspect of living not an isolated episode with a clear beginning and end With this approach and with a better appreciation that symptoms and signs are reactions (sometimes maladaptive) to external or to internal stress, we are beginning to perceive some order in many of the recurrent disorders. When a pattern of illness keeps recurring we become less willing to accept it as an isolated episode and the recurrence as a series of flukes, we seek to identify underlying factors which help to explain them In each individual until the hypothesis is disproved, *we should consider recurrent disorders as the intermittent expressions of persistent disorder*

The search for cause and effect may be philosophically unfashionable nowadays, but it is very useful in medical practice Though for simplicity I separate causes into internal and external groups, it should be emphasised that the two groups are often inseparable and the factors are frequently multiple Man, in health or in disease is a complex of interlocking and integrated mechanisms; if we take him apart to look at them we must remember to put him together again.

Internal factors

Primary organic factors in recurrent disorders. An obvious example is recurrent urinary infection, in which an underlying congenital malformation of the kidney can often be demonstrated. Another is recurrent dislocation of the shoulder in which an anatomical defect (which may have been caused in the first place by injury) can be found in nearly every case

These examples are obvious because the expression of disorder is localised, when it is *not* localised a persistent underlying disorder is more likely to escape notice Recurrent non localised infections are occasionally associated with a deficiency of gammaglobulin, but as an illustration of the multiplicity of factors often involved, recurrent infections are much more commonly associated with poverty malnutrition or over crowding

Order among disorder is likely to escape notice if the manifest disturbances vary from time to time An example is polyarteritis nodosa with recurrent but protean manifestations such as colic, fever asthma anaemia neuritis. Other examples are acute porphyria with its variable episodes of paralysis colicky pain or hysteria, and gout, with its somatic and emotional changes.

Such metabolic disorders are of particular interest because of the varying display of both bodily and emotional disturbances. I mention as another example a child whose predominant disturbance had been considered to be one of behaviour though there was also a history of occasional fits and she suffered from

ordinary food indigestible. In recurrent disorders I suggest that we should think in similar terms of "emotional indigestion." A combination of genetic and environmental factors often determines the type of recurrent disorder, a combination for which I have used the term "family patterning." Good health is the sum of the person's satisfactory adaptation to the total milieu, and failures in adaptation may provoke recurrent expressions of ill-health.

Changing and multiple factors

The time of an underlying, persistent disorder is emphasized by the changing stimuli that may provoke similar recurrent disturbances. The child who reacts to an allergen by developing an asthmatic attack may later react in the same way to infection, often he also learns to react in the same way to emotional stress and apparently to diminishing "doses" of stress, even when the response to allergens is insignificant and infection is absent. Because reaction patterns may become "fixed," even though the provoking factors vary, the study of the aetiology of recurrent disorders should be focussed on the earliest attacks. In later attacks additional factors may confuse and complicate the picture. I wonder whether auto-immune reactions, for example, may come to supersede those which were initiated by hypersensitivity, by infection or by emotional stress.

The realisation that provocative agents may change, and in one person may be multiple and mutually reinforcing, makes a comprehensive approach essential for the doctor.

The Comprehensive Approach

The comprehensive (or psychosomatic) approach *attempts to assess the many factors* that may be concerned in recurrent disorders. This approach *is helpful in* avoiding the errors of over-concentration by the doctor on one part or on one aspect of the person, and in appreciating that organs or *tissues have a limited repertoire* of responses, however diverse the stimuli. "A rash on the hands," it has been neatly said, "might look the same whether it be due to *Dettol*, diesel oil, distaquaine or divorce. The skin fits its owner, and it is the owner who is our patient. If, in the attempt to understand and help him, we take the person to bits for study, we should remember to put the bits together again [4].

My thesis has been that many of the recurrent disorders are intermittent expressions of persistent disorder. In the attempt to understand them we should not restrict our view to a part of the person or to an episode in his life's span. If we broaden our perspective, if we try to include *the complete person in his historical* background, we shall more nearly approach the ideal of "The whole physician for the whole patient."

This must not be taken to minimise the importance of organic causes of recurrent disorders. In children with recurrent abdominal pain an indisputable organic cause can be demonstrated in about 6 to 8 per cent [2] among which renal disease accounts for about half Of children with recurrent headache a very small proportion have a serious underlying disease of the brain or kidneys [1] which it is essential to diagnose and treat promptly But the diagnosis of an organic cause must be no less critically considered than that of an emotional or psychosomatic cause In children with recurrent headache a diagnosis of sinusitis is suspect and nearly always incorrect and most headaches considered to be due to eye strain are in fact, due to emotional strain.

In recurrent disorders the doctor who restricts his enquiries his clinical examination and his investigations to the physical aspects, is also restricting his opportunities of helping the child who has been brought to him Organic disease should be diagnosed or excluded promptly but there should be no wantonness in inquiry' in case the physician becomes a pathogenic agent in perpetuating illness by his well meaning but never-ending efforts to find a physical cause [9]

External factors

A mysterious aspect of many recurrent disorders is not so much that the symptoms come but that they come and then go Why is the pain associated with hydronephrosis often recurrent rather than permanent? Why is acute recurrent porphyria not chronic porphyria? Why do little bellyachers have abdominal pain only at times?—though these episodes may be predictable Why do so many physical and psychogenic disorders, like volcanoes, erupt only occasionally? We know only a little about the compensating mechanisms that attempt to maintain or restore the homeostasis of body and mind, but it is clear that external agents can transform a potential internal weakness into actuality bring to light from time to time a disorder that was hidden, or provoke exacerbations. The environment in which we live and to which we are continually adapting is not exclusively physical but also emotional and social and the reactions of a person to the environment are excited not only through physical media but also through the mind.

In some instances the recurrence of disorder in the child merely reflects the recurrence of an outside stimulus, in the home school or social environment An example is the girl with thyrotoxicosis previously mentioned. Another is that of a boy who had severe abdominal pain with marked pallor each time his mother took him by car to his boarding school at the start of a school term On one occasion, when she drove him to school during the summer vacation to collect his cricket bat he had no pain In some children recurrent disorders can be linked with occasions on which they are unduly excited. recurrent vomiting or asthma often occurs at Christmas or other parties, or on birthdays or at the start of school term

When a patient suffers from recurrent indigestion we need to enquire about dietary indiscretions we appreciate that he may have eaten something which could upset any stomach but we appreciate also that he may have some internal disorder inborn or acquired, which makes even

Developmental Hyperactivity

by HARRY BAKWIN

Developmental Hyperactivity

Developmental disorders account for many of the everyday problems in children. Those which influence behavior relate principally to the control of motility and the acquisition and proper use of the language functions. Enuresis may also be included in this category.

The developmental disorders are inborn deviations in the organization of cerebral function. The clinical manifestations simulate those produced by cerebral lesions, but no changes in the brain can be found. There are no characteristic electroencephalographic patterns.

The disorders are interrelated and familial. Any combination is possible in the individual and the family. Delayed development of speech, specific reading disability (developmental dyslexia) and spelling disability are frequently observed in the same individual. It is common to find that the father of a child with developmental dyslexia is a slow reader and poor speller.

Boys are affected much more often than girls. There is no relation to the intellectual status, the economic status, race or ethnic origin. A severe emotional reaction may accompany the disorder and dominate the clinical picture.

Spontaneous improvement takes place during adolescence. In some instances the improvement is complete and here one may speak of a developmental delay. Some children are not ready to read until they are 8 or 10 years of age [1]. They then start to read and catch up to their age peers quickly. In others improvement takes place but the deviation persists throughout life, although in attenuated form.

The developmental disorders of motility include delay in beginning to walk, abnormal clumsiness, alterations in lateral dominance and hyperactivity.

Symptoms

Hyperactivity of a degree sufficient to create a problem at home and in school, is a frequent complaint voiced by parents [2, 3]. The symptom is often noticed during infancy. Mothers complain that they have difficulty holding the infant, that he seems to want to spring out of their arms, that he will not remain in the play pen. Occasionally the hyperactivity is not observed until later, anywhere up to 6 years according to Laufer & Denhoff [2]. The hyperactivity may not present a serious problem until the child enters school and is expected to sit still there.

The hyperactive child is continually on the move, rushing about from morning

Developmental Hyperactivity

by HARRY BAKWIN

Developmental Hyperactivity

Developmental disorders account for many of the everyday problems in children. Those which influence behavior relate principally to the control of motility and the acquisition and proper use of the language functions. Enuresis may also be included in this category.

The developmental disorders are inborn deviations in the organization of cerebral function. The clinical manifestations simulate those produced by cerebral lesions, but no changes in the brain can be found. There are no characteristic electroencephalographic patterns.

The disorders are interrelated and familial. Any combination is possible in the individual and the family. Delayed development of speech, specific reading disability (developmental dyslexia) and spelling disability are frequently observed in the same individual. It is common to find that the father of a child with developmental dyslexia is a slow reader and poor speller.

Boys are affected much more often than girls. There is no relation to the intellectual status, the economic status, race or ethnic origin. A severe emotional reaction may accompany the disorder and dominate the clinical picture.

Spontaneous improvement takes place during adolescence. In some instances the improvement is complete and here one may speak of a developmental delay. Some children are not ready to read until they are 8 or 10 years of age [1]. They then start to read and catch up to their age peers quickly. In others improvement takes place but the deviation persists throughout life, although in attenuated form.

The developmental disorders of motility include delay in beginning to walk, abnormal clumsiness, alterations in lateral dominance and hyperactivity.

Symptoms

Hyperactivity of a degree sufficient to create a problem at home and in school, is a frequent complaint voiced by parents [2, 3]. The symptom is often noticed during infancy. Mothers complain that they have difficulty holding the infant, that he seems to want to spring out of their arms, that he will not remain in the play pen. Occasionally the hyperactivity is not observed until later, anywhere up to 6 years according to Laufer & Denhoff [2]. The hyperactivity may not present a serious problem until the child enters school and is expected to sit still there.

The hyperactive child is continually on the move, rushing about from morning

until night without let-up. He is uncom fortable when quiet He plays harder and with more zest than his peers and seems to enjoy himself more. He continually explores his environment he takes his toys apart he annoys his parents and play mates. Parents describe him as wound up and in perpetual motion

A number of other behavioral symptoms frequently accompany the hyper activity—distractibility or difficulty in concentrating short attention span, vari able performance of school work, excellent one day poor the next; impulsiveness, that is, acting without premeditation, low frustration level or impatience

The short attention span and distractibility may interfere seriously with school performance The child s attention cannot be sustained long enough for him to listen to the teacher s questions, assignments and other classroom work and consequently his work suffers Many however do well at school

The children are often considered clumsy because they cannot manage buttons and the like and because they are destructive Actually they are frequently unusually agile at climbing trees and the like Their apparent clumsiness is due to haste, impatience and a low frustration level

In some children the speech is rapid, hurried and difficultly understandable The child is in a hurry with his speech as with his other activities. Occasionally there is cluttering speech another devel opmental disorder

Another type of hyperactivity is also frequently met with in children This con sists of a general restlessness, a continual swinging of the leg difficulty in sitting still squirming It is unaccompanied by the other symptoms of the hyperactivity syndrome

Despite their exasperating behavior children with the hyperactivity syndrome are often kind obliging and eager to please The schoolage children become aware of the undesirability of their behavior and are concerned.

Parents find the hyperactive child diffi cult to manage The natural parental affec tion is repeatedly challenged by behavioral difficulties at home in the neighborhood and at school Sooner or later hostile parental attitudes emerge to which the child reacts by an intensification of the hyperactivity and other behavioral distur bances.

Specific learning difficulties often ac company the hyperactivity [4] The chil dren have been found to be inferior to control children in visual motor skills perceptual speed level of sensory motor development and attentiveness. They tend to respond to wrong cues and fail to respond to correct ones. In addition they have difficulty in processing auditory in formation. A slow diffuse dysrhythmia in the electroencephalogram was found in about half the cases studied by Werry and co-workers [5] Its significance is not clear As possible causes they suggest a matura tional disorder a psychophysical effect and brain damage

Hyperactivity is about 4 times as com mon in boys as in girls It i ompatible with a high order of intelligence There are no data on family incidence

Differential Diagno i

The hyperactivity is cons i l to be developmental when a histor f rebral

damage and neurologic signs is absent. It is by far the most frequent type of hyperactivity seen in children. The wide variability in children's activity has already been observed shortly after birth [6, 7, 8]. In a study of infants during the first 2 weeks of life Irwin [6] found that the most active infant in his group was almost 300 times as active as the least active one. It is conceivable that developmentally hyperactive children represent a group which falls at the upper end of a normal curve of variability but this appears unlikely since the group seems sharply demarcated.

A history of difficult labor is of doubtful significance in infants born at term. Full-term infants tolerate anoxia well. Fraser and Wilks [9] followed 60 infants with severe neonatal anoxia. None developed hyperactivity later on. Minde & Webb [10] compared the birth histories of 56 hyperactive children with a similar number of controls. They conclude that "the hypothesis that chronic hyperactivity is frequently the result of complications of pregnancy and delivery receives little support from this study."

Cerebral damage as a cause of the hyperactivity is suspected when there is a history of cerebral injury or disease and when neurologic signs are present. Infants born prematurely, especially the smaller ones, and infants born to mothers who bled during pregnancy or who were toxemic often show neurologic and behavioral sequelae [11]. The hyperactivity in children with cerebral damage has the same character as that seen in developmental hyperactivity but it is ordinarily more intense.

Hyperactivity is often a prominent symptom in children with reactive behavioral disorders. The hyperactivity appears later than in the case of developmental hyperactivity or cerebral damage; it is less intense and not as continuous, being interspersed with periods of quiescence. It is ordinarily not associated with distractibility and short attention span. Usually emotionally disturbing circumstances are present in the home or school.

Early infantile autism. Aside from the fact that children with the hyperactivity syndrome, in contrast to autistic children, relate well to persons, the hyperactivity in children with early infantile autism is distinctive and readily distinguishable from other types of hyperactivity. The movements of the autistic child are rhythmic, repetitious and purposeless—a back and forth pacing, a whirling, a body rocking. The movements are often accompanied by a flapping of the hands and bizarre movements of the fingers. The periods of activity are interspersed with periods of inactivity when the child will sit quietly for long periods watching a revolving phonograph or fan or looking off into space as though deep in thought.

Children with hyperthyroidism are usually overactive. The diagnosis is suspected when the clinical manifestations of hyperthyroidism are present—exophthalmos, palpable thyroid, excessive sweating, rapid pulse and weight loss.

Prognosis

The condition is self limited. The excessive activity usually subsides during early adolescence, occasionally earlier. It has been observed up to 18 years. The other manifestations may persist but are better controlled.

until night without let-up He is uncomfortable when quiet. He plays harder and with more zest than his peers and seems to enjoy himself more He continually explores his environment he takes his toys apart he annoys his parents and playmates. Parents describe him as 'wound up and in perpetual motion

A number of other behavioral symptoms frequently accompany the hyperactivity—distractibility or difficulty in concentrating short attention span variable performance of school work excellent one day poor the next, impulsiveness, that is, acting without premeditation low frustration level or impatience

The short attention span and distractibility may interfere seriously with school performance The child s attention cannot be sustained long enough for him to listen to the teacher s questions, assignments and other classroom work and consequently his work suffers Many however do well at school

The children are often considered clumsy because they cannot manage buttons and the like and because they are destructive Actually they are frequently unusually agile at climbing trees and the like Their apparent clumsiness is due to haste impatience and a low frustration level

In some children the speech is rapid hurried and difficultly understandable The child is in a hurry with his speech as with his other activities. Occasionally there is cluttering speech, another developmental disorder

Another type of hyperactivity is also frequently met with in children This consists of a general restlessness, a continual swinging of the leg difficulty in sitting still squirming It is unaccompanied by the other symptoms of the hyperactivity syndrome

Despite their exasperating behavior children with the hyperactivity syndrome are often kind, obliging and eager to please. The schoolage children become aware of the undesirability of their behavior and are concerned

Parents find the hyperactive child difficult to manage The natural parental affection is repeatedly challenged by behavioral difficulties at home in the neighborhood and at school. Sooner or later hostile parental attitudes emerge to which the child reacts by an intensification of the hyperactivity and other behavioral disturbances.

Specific learning difficulties often accompany the hyperactivity [4] The children have been found to be inferior to control children in visual motor skills perceptual speed level of sensory motor development and attentiveness. They tend to respond to wrong cues and fail to respond to correct ones. In addition they have difficulty in processing auditory information. A slow diffuse dysrhythmia in the electroencephalogram was found i about half the cases studied by Werry an co-workers [5] Its significance is not clear As possible causes they suggest a maturational disorder a psychophysical effec and brain damage

Hyperactivity is about 4 times as common in boys as in girls. It is compatible with a high order of intelligence There are no data on family incidence

Differential Diagnosis

The hyperactivity is considered to be developmental when a history of cerebral

A number of unfavorable side-effects accompany amphetamine administration. A temporary loss of appetite and poor sleep are not infrequent. Sometimes the children acquire a pale, pinched, serious expression with hollows under the eyes. Bad taste in the mouth and fetor oris may also be present. These are generally not sufficient reasons for stopping medication.

Indications to discontinue the drug are exaggeration of the symptoms of the hyperactivity syndrome, epigastric pain, headache and finger tremors.

The drug is given for 8 weeks and then gradually tapered off. The improved behavior during this time helps to resolve conflicts at home and at school, thereby lessening the secondary factors which ordinarily increase the symptoms.

If the symptoms recur the drug may be given again.

Deanol (Deaner) in graded doses starting with 25 mg once a day and increasing to 100 mg, if necessary *is also effective.* It has no known adverse effects.

Chlorpromazine is effective in some cases [13]. It must be given in adequate dosage. For a child 6 years and over an initial dose is 20 mg (2 teaspoons of the syrup of thorazine) 3 times a day. The dose is increased to 150 mg a day if necessary. The parents should be warned that the child may be sleepy for a day or two after the drug is introduced. This wears off quickly.

Management

The first step is an explanation to the parents of the nature of the deviant behavior If possible both parents should be present They should be told that the excessive activity is an inborn characteristic and that it is not wilful misbehavior Asking the parents at this point to enumerate the youngster s favorable qualities serves to emphasize to them that, despite his frequently exasperating behavior their child is basically a good youngster

The parents are told, further that the child s behavioral symptoms are not due to their mismanagement Parents tend to blame themselves for any aberration in their child s behavior It is a great source of comfort for them to have an explanation of the true nature of the behavioral deviation and to be relieved of feelings of guilt and inadequacy The parents are further told about the favorable outcome.

The family situation should be reviewed and corrective suggestions made as indicated. Nagging injunctions to sit still and punishments are useless. Parental conflicts about management should be clarified. A well-ordered routine with a minimum of distractions helps greatly to reduce confusion.

Some hyperactive children do better in a progressive school where freedom of movement is permitted. For most, however a strict regimen with clear-cut rules and definite assignments is preferable Since the attention span is short the assigned tasks should be short enough so that they can be completed. Concrete tasks are better handled than abstract ones.

To minimize distractions classrooms should be void of pictures on the walls and clocks. Window curtains should be drawn. Seats should be widely spaced.

The diagnosis of minimal cerebral damage has become a popular one and psychologists are labelling hyperactive children in this way much too freely This diagnosis is naturally highly distasteful to parents. Although the criteria for a diagnosis of developmental hyperactivity are not as precise as one would like in the absence of a definite history of cerebral injury and in the absence of neurologic signs, parents should be told that there is no reason to suspect cerebral damage

Medication , Amphetamine introduced by Bradley [12] is generally regarded as specific for the treatment of the hyperactivity syndrome whether due to a developmental disorder or cerebral damage A favorable response is regarded by many as supportive evidence for either of these diagnoses [2] A prompt reduction in activity and a better sustained attention span may be expected

The amphetamines are available in two forms, the racemic form (benzedrine sulfate) and as dextro-amphetamine (dexedrine) In some children one form is effective and not the other in others both forms are equally effective The dosage of dexedrine is about half that of benzedrine

As an initial dose for children 6 years and older 10 mg of benzedrine or 5 mg of dexedrine is given after breakfast The dose is increased if necessary every 2 or 3 days until a therapeutic or toxic effect is produced. A clinical effect is observed in 20 to 30 minutes. A second dose later on the day may be given if the early favorable effect wears off Dexedrine is available in spansule form which permits gradual release of the drug

Methämoglobin rasch reduzierten und Zellen, die das nicht tun.

Bereits auf dem Internationalen Hämatologenkongreß in Stockholm 1964 wurden jedoch Zweifel laut, ob mit der zytologischen Methodik das hypothetische Zellmosaik sichtbar gemacht wird [7–10]. Frischer *et al.* [7] fanden bei sorgfältigen Verlaufskontrollen der Reduktion in Anwesenheit von Methylenblau und Glukose je nach dem Zeitpunkt der Prüfung ein anderes Verhältnis von reduzierenden und nichtreduzierenden Zellen, ein Ergebnis, das der Auffassung von zwei definierten Zellpopulationen widerspricht. Wir entschlossen uns daher, dieser Frage in erneuten Untersuchungen nachzugehen.

Methodik

Als Basis für die Versuche benutzten wir den Brewer-Test [4]: 2 ml Citratblut werden mit 0,1 ml 1,25% Natriumnitrit, 0,1 ml 0,5 10^{-3} mol Methylenblau und 0,1 ml 5% Glukose versetzt und bei 37° inkubiert. Zu verschiedenen Zeiten wurden Proben zur zytologischen Untersuchung und Methämoglobinbestimmung entnommen. Die Originalanweisung von Brewer *et al.* [4] wurde je nach dem Untersuchungszweck gelegentlich modifiziert. Für eine Anzahl Versuche wurde statt Methylenblau eine äquimolare Lösung von Nilblausulfat verwendet.

Die *Methämoglobinbestimmung* wurde nach Evelyn und Malloy [6] durchgeführt; in jedem Fall wurden die Erythrozyten vor der Hämolyse gewaschen. Der zytologische *Methämoglobinnachweis* erfolgte nach Kleihauer und Betke [8].

Als *Träger des G-6-PD-Mangels* standen uns einige Patienten unserer Klinik zur Verfügung. Ob es sich um Kinder italienischer und griechischer Abstammung handelt. In allen Fällen lag die "kaukasische Variante" des G-6-PD-Mangels mit praktisch völlig fehlender Enzymaktivität bei den männlichen Probanden vor. Die Mütter erwiesen sich nach dem Ergebnis der Enzymbestimmung als heterozygot. Außerdem verdanken wir Herrn Professor Waller die Möglichkeit, daß wir Untersuchungen an Mitgliedern einer deutschen *Familie mit G-6-PD-Mangel* durchführen konnten.

Ergebnisse

Methämoglobinbildung im Brewer-test [4]. *Nach Zusatz* der Reagenzien erfolgte in sämtlichen Blutproben eine rasche Methämoglobinbildung (Abb. 1). Bei normalen *Versuchspersonen* war nach 40–60 Minuten das Maximum erreicht mit Werten zwischen 0–90%. Methämoglobin. Heterozygote *Frauen* verhielten sich ähnlich, erreichten aber meist einen etwas höheren Maximalwert und etwas später als die *Kontrollen. Bei hemizygoten Jungen stieg* der Wert noch bis zur dritten Stunde an und verblieb dann auf einer Höhe zwischen 97 und 100%.

In zwei Versuchen wurde Nitrit 15 Minuten vor Zusatz von Glukose und Methylenblau in das Blut eingebracht. Dies änderte am Ablauf der Oxydation nicht viel.

Ablauf der Methämoglobinreduktion. Bei den Kontrollen erfolgte die Methämoglobinreduktion in ihrem Hauptanteil in der zweiten Stunde und *führte mit dem* Ablauf von drei Stunden zu Werten unter 10% Methämoglobin (Abb. 1 und 2). Bei hemizygoten Jungen blieb der *Methämoglobinwert* über viele Stunden unverändert in der Nähe von 100%. Die heterozygoten Frauen verhielten sich intermediär, *zeigten* aber erhebliche Unterschiede in der Reduktionsgeschwindigkeit (Abb. 2). Eine künstliche Mischung von normalen Erythrozyten und Erythrozyten eines hemizygoten Pa-

Aus der Univ Kinderklinik Tübingen Direktor Prof Dr K. Betke

Zytologische Untersuchungen zur Frage des Zellmosaiks bei heterozygoten Frauen mit Glukose 6 Phosphatdehydrogenase Mangel

von K. BETKE, E. KLEIHAUER und Z. KNOTEK

Bei Glukose-6-Phosphatdehydrogenase (G-6-PD)-Mangel ist es schwierig Heterozygote sicher zu erfassen Da es sich um ein X chromosomal vererbtes Leiden handelt kommen nur Frauen als Heterozygote in Frage. Die Enzymaktivität weist bei solchen Personen erfahrungsgemäß eine *große Schwankungsbreite* auf. Der für Screening Untersuchungen so wertvolle Motulsky Farbtest ist in dieser Beziehung unzuverlässig aber auch die spektrophotometrische Messung der Enzymaktivität läßt häufig im Stich Zu dieser Frage wurde von Choremis *et al* [6] ein großes und aufschlußreiches Material geliefert. In einer breit angelegten Untersuchung fanden sie *bei 49 Müttern* von hemizygoten Jungen, also bei mutmaßlich heterozygoten Frauen, Enzymaktivitäten von Null bis nahe an die untere Grenze der Norm Im Einzelfall war es oft unmöglich zu entscheiden, ob eine Mutter homo- oder heterozygot war während — im Gegensatz zu den Verhältnissen beim G 6-PD Mangel der Neger — die Abgrenzung von heterozygoten Frauen gegen Gesunde weniger schwierig war

Eine interessante neue Möglichkeit zur Untersuchung heterozygoter Frauen ergibt sich aus zytologischen Studien. Wenn die von Lyon *aufgestellte* Hypothese zutrifft, *müßten bei heterozygoten* Frauen mit G 6-PD-Mangel *zwei* Erythrozytenpopulationen vorliegen. erstens Erythrozyten *mit normaler Enzymaktivität* zweitens Erythrozyten mit voll ausgeprägtem Defekt. Dies wurde bereits 1962 von Beutler *et al* [3] wahrscheinlich gemacht, indem sie fanden daß die intrazelluläre Reduktion von Methämoglobin in Gegenwart von Methylenblau und Glukose (wofür G-6-PD erforderlich ist) bei heterozygoten Frauen mit G-6-PD Mangel nicht wie in einer einheitlichen Zellsuspension ablief sondern die Existenz zweier verschiedener Zellpopulationen nahelegte Durch die von Kleihauer und Betke [8] entwickelte Methode, Methämoglobin in Erythrozyten eines Blutausstriches zytologisch *nachzuweisen* wurde es möglich dieser Frage direkt nachzugehen. Unabhängig voneinander stellten *Sansone et al [11] und* Tönz und Rossi [13] solche Untersuchungen an und zeigten daß in der Tat bei der Methämoglobinreduktion in Anwesenheit von Glukose und Methylenblau bei heterozygoten Frauen zwei Populationen von Erythrozyten auftraten Z[illegible] die

Abb. 1. Methämoglobinbildung und Methämoglobinreduktion im Brewer-Test. Eine künstliche Mischung von Blut des hemizygoten Patienten mit Kontrollblut verhält sich ähnlich wie das Blut der heterozygoten Mutter

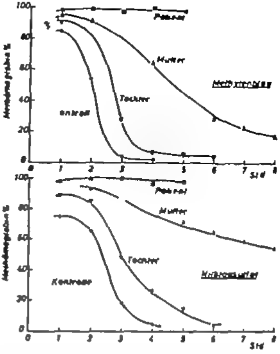

Abb. 2. Methämoglobinreduktion im modifizierten BREWER-Test. Die Mutter und Tochter des hemizygoten Probanden sind beide heterozygot (Familie von Waller et al. 1966). Versuchsbedingungen: 2 ml Citratblut + 0,1 ml 1,5% Natriumnitrit; nach 15 Minuten Zusatz von 4,0 ml Kochsalz-Phosphat pH 7,0, 0,3 ml 1 · 10⁻⁴ mol Methylenblau oder Nilblausulfat, 0,3 ml 5% Glucose. 37°, O_2-Atmosphäre durchschüttelt in.

tienten zeigte prinzipiell den gleichen Reduktionsablauf wie Erythrozyten einer heterozygoten Frau (Abb. 1). Eine zweiphasische Kurve, wie man sie an sich hätte erwarten können, war nicht zu erkennen.

Wurde Nilblausulfat statt Methylenblau verwendet, verlief die Reduktion insgesamt etwas langsamer. Abgesehen davon war jedoch kein grundsätzlicher Unterschied gegenüber den Verhältnissen mit Methylenblau zu erkennen (Abb. 2).

Einige Blutproben wurden zunächst mit Nitrit behandelt, nach Methämoglobinbildung auf der Zentrifuge gewaschen und anschließend mit Glukose und Methylenblau inkubiert. Die Reduktion verlief in diesen Ansätzen wesentlich schneller als in Ansätzen mit Anwesenheit von Nitrit, wie es dem Brewer-Test entspricht. Auch hemizygote Jungen zeigten eine langsame, aber eindeutige Reduktion. Weder bei heterozygoten Frauen noch in Mischungen konnte eine zweiphasische Kurve festgestellt werden.

Zytologische Ergebnisse. Bei der verwendeten Methode wird aus Erythrozyten, die Methämoglobin enthalten, der Blutfarbstoff herausgelöst, während Erythrozyten mit Oxyhämoglobin (bzw. reduziertem Hämoglobin oder auch Carboxyhämoglobin) ihren Farbstoff behalten. Leere Zellen sind also gleichbedeutend mit Methämoglobin-Zellen, volle Zellen gleichbedeutend mit Oxyhämoglobin-Erythrozyten.

In Blutproben von *Normalpersonen* fanden sich im Brewer-Test mit Methylenblau auf der Höhe der Methämoglobinbildung

1 Stunde

nach 1 Stunde überwiegend Methämoglobin-Zellen, also leere Stromata; in jedem Fall aber auch einige volle Zellen und einige Intermediärformen, von denen man annehmen muß, daß in ihnen der Blutfarbstoff nur teilweise in Methämoglobin umgewandelt ist. Nach 2 Stunden war die Hälfte der Zellen oder mehr voll, ein Teil intermediär, der Rest leer. Nach 3 Stunden lag abgesehen von vereinzelten leeren oder intermediären Zellen eine einheitliche Population von vollen, also Oxyhämoglobin-Zellen vor. Wurde statt Methylenblau Nilblausulfat verwendet (Abb. 3), dann war der Verlauf etwas langsamer. In diesem Fall waren nach 4 Stunden mit vereinzelten Ausnahmen alle Zellen voll.

Hemizygote Jungen hatten nach 1 Stunde gelegentlich noch einzelne volle Zellen, spätestens nach 2 Stunden war jedoch eine einheitliche Population von leeren Zellen, also Methämoglobin-Zellen vorhanden. Dies blieb über viele Stunden unverändert so. Eine einzelne Oxyhämoglobin-Zelle konnte jedoch gelegentlich gesehen werden (Abb. 3, 5 Stunden). Mit Nilblausulfat wurden die gleichen Resultate erzielt wie mit Methylenblau.

Heterozygote Frauen hatten ähnlich wie Normalpersonen nach 1 Stunde neben leeren Zellen stets auch einige volle Zellen. Im Ablauf der Reduktion mit Methylenblau vermehrten sich die vollen Zellen, jedoch nicht so schnell wie bei den normalen Kontrollen. Auch intermediäre Zellformen wurden gesehen. Die Relation von vollen zu leeren Zellen verschob sich langsam zugunsten der vollen Zellen. Nach 5–6 Stunden waren die leeren Zellen verschwunden oder nur noch in geringer Zahl vorhanden. Bei Verwendung von Nilblausulfat (Abb. 3) war der Ablauf insofern etwas anders, als sich das nach 2–3 Stunden erreichte Verhältnis von vollen zu leeren Zellen über weitere 2–3 Stunden annähernd konstant hielt. Auch hier traten intermediäre Zellformen auf und es sank schließlich auch die Zahl der leeren Zellen. Dies war vor allem dann deutlich, wenn von vornherein die Zahl der vollen Zellen rascher zugenommen hatte (Abb. 3, Serie der Tochter).

Künstliche Mischungen aus Erythrozyten von hemizygoten Jungen und Normalerythrozyten verhielten sich ebenso wie Erythrozyten von heterozygoten Frauen. Auch in diesem Fall nahm im Lauf der

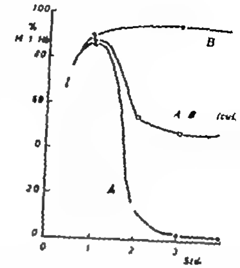

Abb. 4. Errechneter Verlauf der Methämoglobinreduktion in einer künstlichen Mischung (A + B) von Normalblut (A) mit Blut eines Hemizygoten (B), wenn die beiden Erythrozytenpopulationen unabhängig voneinander reagieren. Vergleiche hiermit den tatsächlichen Verlauf in Abb. 1

Abb. 3. Zytologische Befunde im Ablauf des modifizierten Brewer-Testes über 6 Stunden. Von oben nach unten: 1 = Normaler Erwachsener, 2 = Hemizygoter Mann (Patient von Prof. W. Keller), 3 = Mutter von 2, heterozygot, 4 = Tochter von 3, heterozygot, 5 = Künstliche Mischung von 1 und 2. — Versuchsbedingungen wie in Abb. 2

Inkubation die Zahl der vollen Zellen zu und die der leeren Zellen ab, und es traten auch intermediäre Zellen auf. Mit Nilblausulfat wurde das Bild von zwei Zellpopulationen länger aufrecht erhalten als mit Methylenblau (Abb. 3).

Besprechung

Was erwartet man von einem Zellmosaik mit zwei Populationen von Erythrozyten, aktiven und inaktiven, bei der Reduktion im Brewer-Test? Wenn beide Erythrozytenarten ohne gegenseitige Beeinflussung reagieren, mußte die in Abbildung 4 gezeichnete Kurve resultieren: eine Reduktion bis auf einen mittleren Methämoglobinwert und dann ein Verharren auf dieser Höhe. Die tatsächlichen Versuchsergebnisse liefern nie solche Kurven (vgl. Abb. 4 mit Abb. 1). Dies zeigten bereits Beutler und Baluda [2] 1963 für die Reduktion mit Methylenblau und Glukose nach Auswaschen von Nitrit.

Da die Reduktion weiterläuft, als man erwarten sollte, muß man annehmen, daß die normalen Erythrozyten den defekten Erythrozyten eine Stoffwechselhilfe leisten. Nach Untersuchungen von Banaschak und Schaler [1] sowie von Beutler und Baluda [ ] ist es sehr wahrscheinlich, daß Leukomethylenblau der Mediator ist. Wenn die normalen Zellen mit Hilfe des Methylenblau-Leukomethylenblau-Wechsels ihr eigenes Methämoglobin reduziert haben, fahren sie fort, Leukomethylenblau zu bilden, welches dann den defekten Zellen als Reduktionsmittel zur Verfügung steht. So kann man sich den Mechanismus vorstellen.

Wir haben versucht, dieser „Stoffwechselhilfe“ dadurch entgegenzuwirken, daß wir die Reaktion in reiner O_2-Atmosphäre unter ständigem Durchmischen der Blutprobe und mit verdünnten Ansätzen durchführten. Durch Sauerstoff und Verlängerung des Weges von einem zum anderen Erythrozyten sollte Leukomethylenblau oxydiert werden, bevor es einen anderen Erythrozyten erreicht. Einen eindeutigen Effekt konnten wir jedoch nicht feststellen.

Entsprechend dem Verhalten der Methämoglobinwerte verschwinden auch in der zytologischen Auswertung bei längerer Dauer die „leeren“ Zellen in Mischungen von defekten und normalen Zellen. Wenn die beiden Erythrozytenpopulationen voneinander unabhängig wären, mußte man nach 3–4 Stunden ein stabiles Verhältnis von „leeren“ zu „vollen“ Zellen haben, und es dürften auch keine intermediären Zellformen in größerer Zahl auftreten. Die tatsächlichen Befunde sind wie berichtet anders. Das zytologische Bild nach 4 oder 5 Stunden zeigt also nicht exakt das Verhältnis von normalen zu defekten Zellen an. Zwar darf man annehmen, daß Zellen, die nach 5 Stunden „leer“ sind, keine G-6-PD-Aktivität besitzen, doch sind unter den „vollen“ Zellen nicht nur normal aktive Zellen, sondern zweifellos auch einige defekte Zellen, denen geholfen wurde.

Beutler und Baluda [2] hatten festgestellt, daß bei Verwendung von Nilblausulfat anstelle von Methylenblau der Effekt der Stoffwechselhilfe nicht auftritt. Dies können wir nicht bestätigen, wenn wir die Methämoglobinwerte betrachten (Abb. 2). Auch in diesem Fall läuft die Reduktion weiter, allerdings langsamer als bei Verwendung von Methylenblau. In der zytologischen Auswertung fanden wir jedoch eine gewisse Stabilität von zwei Populationen über ~ bis 3 Stunden (Abb. 3).

Diese Feststellung widerspricht nur scheinbar der ersten. Die Urteile „leer", „voll" und „intermediär" erlauben nur einen groben Rückschluß auf die Menge an vorhandenem Methämoglobin, so daß der Methämoglobingehalt insgesamt abnehmen kann, obwohl die Zahl der leeren und vollen Zellen annähernd konstant bleibt. Einschränkend müssen wir allerdings sagen, daß wir bisher noch keine exakten Auszählungen der leeren und vollen Zellen durchgeführt haben.

Aus den Untersuchungsergebnissen kann man den Schluß ziehen, daß weder der Ablauf der Methämoglobinreduktion noch das zytologische Bild zu irgendeinem Zeitpunkt exakt die postulierten beiden Erythrozytenpopulationen bei heterozygoten Trägerinnen des G-6-PD-Mangels aufzeigen. Insofern ist die Kritik von Frischer *et al.* [7] und Salvidio *et al.* [10] berechtigt. Andererseits ist es korrekt zu sagen, daß Erythrozyten von heterozygoten Frauen sich ebenso verhalten wie eine künstliche Mischung von defekten und normalen Erythrozyten. Dies ist zwar kein schlüssiger Beweis für die Lyon-Hypothese [9], aber ein starkes Argument für sie.

Für praktische Belange ist es wichtig zu entscheiden, ob eine Frau heterozygot, homozygot oder gesund ist. Dies kann der zytologische Test leisten. Insbesondere dürfte die von Choremis *et al.* [5] herausgestellte, in Europa wichtige Unterscheidung von Heterozygotie und Homozygotie einwandfrei möglich sein.

Hierzu bedarf es einer gewissen Standardisierung der Methodik. In jedem Fall ist notwendig, daß im Testansatz Nitrit anwesend ist (wie es der Brewer-Test vorschreibt), weil anderenfalls die Methämoglobinreduktion über den Hauptweg der Glykolyse störend ins Spiel kommt. Nilblausulfat ist nach den mitgeteilten Ergebnissen dem Methylenblau vorzuziehen. Noch nicht sicher belegen können wir unsere Auffassung, daß es nützlich ist, das Blut im Ansatz etwas zu verdünnen (wie es die Legende zu Abb. 3 angibt) und durch wiederholtes oder laufendes Schütteln zu verhindern, daß die Erythrozyten sedimentieren.

Die Kombination des Brewer-Testes (mit Nilblausulfat statt mit Methylenblau ausgeführt und nach 4 Stunden statt nach 3 Stunden geprüft) mit der zytologischen Auswertung eines nach 4 Stunden hergestellten Ausstriches dürfte für Routinezwecke eine äußerst leistungsfähige Methode zur Erfassung von Heterozygoten sein. Wie bei allen anderen Testmethoden ist das Verhalten der Erythrozyten von Heterozygoten auch im zytologischen Bild sehr variabel (Abb. 3: Mutter und Tochter des hemizygoten Probanden). Die Zytologie hat jedoch gegenüber den anderen Methoden, die lediglich eine pauschale quantitative Aussage über das gesamte Zellkollektiv machen, den Vorteil, das individuelle Verhalten der Zellen zu berücksichtigen. Daraus kann im Einzelfall eine entscheidende Information gewonnen werden.

Zusammenfassung

Bei der Durchführung des Brewer-Testes mit Blut von heterozygoten Frauen mit G-6-PD-Mangel nahm im zytologischen Präparat die Zahl der methämoglobinhaltigen Zellen im Ablauf der Zeit kontinuierlich ab, die der oxyhämoglobinhaltigen Zellen zu. Die Befunde sind nicht geeignet, die Existenz zweier definierter Zellpopulationen zu beweisen. In gleicher

Weise verhielten sich jedoch künstliche Mischungen von Normalblut mit Blut hemizygoter Träger der Anomalie. Offensichtlich leisten die normalen Erythrozyten den defekten Erythrozyten eine metabolische Hilfe. Diese wird wahrscheinlich durch Leukomethylenblau vermittelt. Wenn Nilblausulfat statt Methylenblau verwendet wurde, war eine Existenz zweier Zellpopulationen im Blut heterozygoter Frauen und in künstlichen Mischungen besser erkennbar. Unter standardisierten Bedingungen ist die Kombination des Brewer Testes (mit Nilblausulfat durchgeführt) mit der zytologischen Auswertung eines nach 4 Stunden hergestellten Ausstriches eine wertvolle Hilfe für die Erkennung von Heterozygoten.

Summary

During the course of the Brewer test in blood of heterozygous females with G-6-PD-deficiency the count of methaemoglobin containing cells decreased with time while the count of oxyhaemoglobin containing cells increased. There was, therefore no clear-cut evidence for the existence of two definite cell populations as postulated by the Lyon-hypothesis [9]. However the same findings were seen in *artificial mixtures of normal blood with* blood of hemizygous males. Apparently the normal cells give metabolic aid to the deficient cells. This is probably mediated by leukomethylene blue. With Nile blue sulfate instead of methylene blue the evidence for the existence of two cell populations was somewhat better. Under standardized conditions the combination of the Brewer test (done with Nile blue sulfate) with the cytological evaluation of a smear prepared after 4 hours is a valuable diagnostic aid for the detection of heterozygotes.

Diese Feststellung widerspricht nur scheinbar der ersten. Die Urteile „leer", „voll" und „intermediär" erlauben nur einen groben Rückschluß auf die Menge an vorhandenem Methämoglobin, so daß der Methämoglobingehalt insgesamt abnehmen kann, obwohl die Zahl der leeren und vollen Zellen annähernd konstant bleibt. Einschränkend müssen wir allerdings sagen, daß wir bisher noch keine exakten Auszählungen der leeren und vollen Zellen durchgeführt haben.

Aus den Untersuchungsergebnissen kann man den Schluß ziehen, daß weder der Ablauf der Methämoglobinreduktion noch das zytologische Bild zu irgendeinem Zeitpunkt exakt die postulierten beiden Erythrozytenpopulationen bei heterozygoten Trägerinnen des G-6-PD-Mangels aufzeigen. *Insofern ist die Kritik von Frischer et al.* [7] und Salvidio *et al.* [10] berechtigt. Andererseits ist es korrekt zu sagen, daß Erythrozyten von heterozygoten Frauen sich ebenso verhalten wie eine künstliche Mischung von defekten und normalen Erythrozyten. Dies ist zwar kein schlüssiger Beweis für die Lyon-Hypothese [9], aber ein starkes Argument für sie.

Für praktische Belange ist es wichtig zu entscheiden, ob eine Frau heterozygot, homozygot oder gesund ist. Dies kann der zytologische Test leisten. Insbesondere dürfte die von Choremis *et al.* [5] herausgestellte, in Europa wichtige Unterscheidung von Heterozygotie und Homozygotie einwandfrei möglich sein.

Hierzu bedarf es einer gewissen Standardisierung der Methodik. In jedem Fall ist notwendig, daß im Testansatz Nitrit anwesend ist (wie es der Brewer-Test vorschreibt), weil anderenfalls die Methämoglobinreduktion über den Hauptweg der Glykolyse störend ins Spiel kommt. Nilblausulfat ist nach den mitgeteilten Ergebnissen dem Methylenblau vorzuziehen. Noch nicht sicher belegen können wir unsere Auffassung, daß es nützlich ist, das Blut im Ansatz etwas zu verdünnen (wie es die Legende zu Abb. 1 angibt) und durch wiederholtes oder laufendes Schütteln zu verhindern, daß die Erythrozyten sedimentieren.

La valeur des différents BCG

par ROBERT DEBRÉ

La valeur du vaccin BCG comme agent de protection contre la tuberculose est acquise aujourd'hui après des discussions passionnées et des études prolongées. Il va de soi que ce vaccin, pas plus qu'aucun autre, ne protège tous les sujets vaccinés sans exception, encore que nous ne sachions pas exactement les causes de ces défaillances vraies de la vaccination. Celle-ci protège généralement contre les manifestations de la tuberculose primaire, la tuberculose miliaire, la méningite tuberculeuse, la pleurésie tuberculeuse, la tuberculose pulmonaire progressive précoce et même semble-t-il, la tuberculose pulmonaire tardive. Sur ces points le Professeur A. Wallgren a rapporté les conclusions de son expérience et montré les limites de notre connaissance dans un intéressant document présenté à la Réunion de la Commission de Prophylaxie de l'Union Internationale contre la Tuberculose à Munich en 1966*.

Mais on n'observe que trop de fausses défaillances: deux sont importantes. La première est liée à une contamination tuberculeuse peu de temps avant ou peu de temps après la vaccination, cette dernière ne peut en empêcher ou en modifier l'évolution. D'autres fausses défaillances du BCG sont liées à une faute dans l'administration de celui-ci, comme par exemple l'exposition à la lumière solaire. Mais la cause de défaillance vraie la plus importante réside dans l'emploi d'un vaccin de médiocre qualité. C'est qu'en effet il n'y a pas actuellement un vaccin BCG mais plusieurs et ils diffèrent entre eux car les souches-filles, toutes issues de la souche Nocard modifiée par Calmette et Guérin, diffèrent entre elles. Sans doute l'innocuité de toutes est reconnue mais leur valeur varie. C'est lorsque furent étudiés les résultats des campagnes de masse entreprises aussitôt après la fin de la deuxième guerre mondiale par les Croix Rouge scandinaves puis l'UNICEF et ensuite l'OMS, que l'on vit des variations dans le degré de l'allergie conférée, que celles-ci étaient très importantes suivant les zones considérées et que leurs causes étaient sans doute multiples et en grande partie liées aux conditions de transport et d'emploi des ampoules. Mais on dut bientôt convenir que jouait aussi l'activité inégale des vaccins issus des divers centres de fabrication, voire des lots successifs provenant d'un même laboratoire [Robert Debré et R. Mande].

Dans le même temps, des travaux expérimentaux mettaient en lumière les variations du BCG. On savait qu'il n'y avait pas et sans doute n'y avait jamais eu la parfaite homogénéité d'une souche

* Bulletin de l'Union Internationale contre la Tuberculose. Vol. XXXVIII, n° 1 juin 1966, p. 7

issue d un seul clone La possibilité de dissociation artificielle du BCG en types R et S avait depuis longtemps été mise en lumière dans le laboratoire même de Calmette [A. Saenz et L. Costil K. Birkhaug] Cette dissociation ne légitimait aucunement la crainte d un retour à la virulence Elle n en était pas moins réelle et représente comme l annonce des travaux ultérieurs sur les différences entre les cultures de BCG entretenues dans les laboratoires variés et des recherches sur les divers types de colonies qui coexistent dans la même culture

En 1946 K. A. Jensen, ayant obtenu par la mesure de la lésion locale du cobaye des résultats différents avec deux échantillons de BCG conclut à une inégalité de virulence entre eux. Mais cette assertion fut contestée et l individualisation de « sous-souches » ou « souches-filles » à caractères séparés ne fut réellement acquise qu à la suite des publications de R Dubos et de ses collaborateurs. Ceux ci montrèrent que les diverses souches-filles n ont pas toutes le même pouvoir immunisant. Même lorsque les caractères étudiés sont sans rapport connu avec l efficacité du vaccin. Les preuves qu elles apportent des différences entre les BCG méritent d être retenues. Mais ce qui compte le plus est actuellement le retentissement sur l activité des vaccins des caractères de chaque souche fille Il ne fut pas admis sans débat. On trouvera dans la monographie de A. Frappier et M. Panisset l exposé des discussions auxquelles la question donna lieu jusqu en 1958 [Monographie de l Institut de Microbiologie de l Université de Montréal Canada, 1957].

Par ailleurs comme R Dubos le faisait observer dès 1949 les suspensions de BCG utilisées pour les vaccinations sont très inégalement riches en unités vivantes. On se rendait ainsi compte peu à peu qu'il restait beaucoup à faire pour rendre la production de BCG plus constante et régulière dans son efficacité. La lyophilisation, proposée en 1944 par A. Leschinskaia ouvre une voie fort importante à cet égard Mais les progrès qu elle autorise risquent de rester incertains si l on n arrive pas à éprouver les vaccins sous la forme même où ils sont administrés à l homme Les recherches à ce sujet sont menées tout d abord dans des laboratoires adonnés chacun au contrôle de sa propre production L étude réalisée à Bergen par E. Krohn [1952] mérite une mention particulière De leur côté K Bikhaug, O Sievers, Orakov et Engback entre autres, s attachent à la description des épreuves qu ils considèrent comme des plus utiles. Des travaux similaires sont entrepris par les auteurs soucieux d évaluer les procédés de lyophilisation qu ils mettaient au point. Parmi eux on signale ceux de T Ebina A. Frappier H Frappier H Humabe et T Sawada Y Obayashi, J Aronson et P Schneider S R Rosenthal J Ungar et coll

Au fur et à mesure que se développent ces investigations, les épreuves proposées se multiplient Tout en consacrant leurs efforts aux comptes d unités vivantes, beaucoup essaient de développer d autres techniques *in vitro* En outre la vérification de l activité des vaccins chez l animal est de plus en plus employée en s inspirant en premier lieu des méthodes qui avaient servi à Calmette Boquet, Nègre et coll dans leurs études fondamentales. L observation des sujets vaccinés n en garde pas

moins sa place et fait encore l'objet de nombreux travaux [R. Mande et A. Huet].

On peut s'étonner alors que l'inégalité possible entre vaccins commence à être reconnue, que les épreuves mises en pratique dans les laboratoires de production ne soient pas rapidement appliquées à l'évaluation simultanée de vaccins d'origines multiples. Mais de telles comparaisons, pour se montrer fructueuses, sont plus difficiles à réaliser que la surveillance d'un type de BCG déterminé et de ses variantes.

Cependant nous nous sommes demandé avec nos collaborateurs s'il n'y avait pas moyen d'éprouver les vaccins en utilisant conjointement l'observation du sujet vacciné et les épreuves de laboratoire. C'est la tâche que poursuit depuis des années la *station-pilote du Centre International de l'Enfance* (F. M. Lévy, Ch. Leblois, A. Huet, D. Schwartz, J. P. Pasquier, Raymond Mande). D'autres études voisines ont été poursuivies par l'OMS (Dr J. Holm et enfin par une expérience de plusieurs laboratoires coordonnée par A. Frappier et M. Panisset). On dispose à présent d'un grand nombre de publications intéressantes sur ce sujet important, à propos desquelles nous voudrions ici exposer quelques remarques.

L'élaboration d'une méthode permettant de déterminer l'activité d'échantillons de BCG de sources variées a été le souci commun des chercheurs du Centre International de l'Enfance, cliniciens et expérimentateurs. Sans que des réponses positives aient pu encore être données à toutes les questions posées, une orientation se dégage des constatations déjà faites. Celles-ci concernent principalement le BCG sec. Il ne paraît pas acceptable de se limiter à une seule épreuve quelle qu'elle soit. La méthode que nous proposons cherche à renseigner sur les principales propriétés du vaccin : concentration en bacilles vivants et en bacilles morts, pouvoir allergisant chez l'homme, pouvoir protecteur chez l'animal. Elle tend aussi à permettre, par la confrontation de tous les résultats, d'aborder la question des rapports, jusqu'à présent mal définis, entre ces différents caractères.

(a) Les *comptes de colonies* représentent, de toutes les épreuves, la plus unanimement considérée comme essentielle. Pour y procéder, Ch. Leblois est parti de la technique de Jensen, à laquelle au terme d'investigations minutieuses, il a apporté divers amendements de nature à en augmenter la précision. Mais les dénombrements, quelle que soit la technique suivie, ne permettent pas en réalité de connaître le nombre des germes vivants présents dans l'échantillon étudié. Il en est, en proportion difficile à déterminer, mais sans doute élevée, qui se développent à partir d'un amas de germes plus ou moins important.

La capacité de multiplication des germes *in vitro* est également jugée par la mesure, effectuée par Pasquier, de la fixation par les germes d'isotopes radioactifs incorporés à un milieu liquide : ^{32}P d'abord, à la suite de Ström et de Tubiana, Costil et Mme V. Drouhet, et maintenant ^{14}C dont l'emploi, sous forme d'acétate de sodium, a d'ores et déjà permis des constatations de quelque portée. D'autre part il a semblé intéressant à F. M. Lévy et [illegible] Conge de recourir à des mesures d'exécution simple, photométriques et volumétriques qui permettent de vérifier sommairement, mais avec une approximation

suffisante la régularité des échantillons étudiés quant à la concentration microbienne globale

(b) L'*expérimentation sur l'animal* permet d'aboutir à des résultats qui renseignent sur certaines propriétés capitales de la préparation injectée La cobaye est irremplaçable dans l'appréciation au laboratoire du pouvoir exercé par le BCG de conférer l'allergie tuberculinique et convient bien aussi pour l'observation de la réaction locale (Jensen, Birkhaug Frappier et Marois, Krohn, etc.) Encore faut-il avoir recours à des techniques de mesure aussi quantitatives que possible

Plus importants sans doute comme critères d'activité sont les tests de protection qui permettent de juger directement de l'efficacité du BCG De telles épreuves peuvent être effectuées sur des espèces variées. Nous avons préféré nous adresser à la souris qui se prête particulièrement bien à l'expérimentation en grande série Ces recherches s'inscrivent à la suite de celles de R. J Dubos et C. H Pierce et ont été menées selon la technique des auteurs quelque peu modifiée grâce aux avis de R. J Dubos. Elle consiste à vacciner la souris par une injection de BCG et à l'éprouver par l'injection ultérieure de bacilles virulents. On peut aussi, en se limitant à l'inoculation de vaccin sans la faire suivre d'une injection d'épreuve étudier la multiplication du BCG dans les organes de l'animal

(c) L'*observation clinique chez l'enfant* est indispensable mais l'obligation ou l'on se trouve de toujours employer des doses à la fois efficaces et non excessives, l'impossibilité de disposer à intervalles rapprochés des sujets, même pour un simple examen clinique représentent une servitude dont nul ne songerait à s'affranchir mais qui empêche parfois de pousser les investigations aussi loin qu'on le voudrait. Les renseignements recueillis n'en sont pas moins du plus haut prix, comme touchant directement au point le plus important les résultats de la vaccination par le BCG telle qu'on la pratique. Certes, il est impossible dans l'état actuel des choses de mesurer l'immunité conférée à l'homme et de comparer à cet égard des vaccins de fabrication différente ou plusieurs échantillons de même origine. Les seuls phénomènes qu'il soit aisé d'étudier chez l'enfant sont la réaction locale de la peau l'allergie tuberculinique. L'observation précise et la mesure à dates fixes tant de la réaction locale que du test tuberculinique effectuées dans des groupes suffisamment nombreux, permettent d'enregistrer des résultats variant d'un vaccin à l'autre L'étude de la persistance de l'allergie renseigne peut-être mieux encore sur les différences entre les échantillons utilisés.

La proportion de virages du « Mantoux » à 5 ou 10 unités (PPD) exprime de la manière la plus simple le pouvoir allergisant du BCG employé. Cependant le résultat peut approcher de 100 même avec des produits d'activité assez médiocre Les dimensions moyennes de l'induration du « Mantoux » (à 5 ou 10 unités PPD) constituent un test plus nuancé D'utiles informations sont obtenues aussi en déterminant la proportion des indurations fortes (types I et II selon la terminologie du Bureau de Recherches sur la Tuberculose de l'Organisation Mondiale de la Santé)

D'autres mesures portent sur les dimensions de la lésion locale après injection intradermique Il convient de déterminer

non seulement la taille de l'induration, mais celle de la réaction érythémateuse [C. Fillastre]. Enfin le pourcentage des adénites, simples ou suppurées, consécutives à la vaccination peut également aider à déceler les différences entre vaccins. Tous ces chiffres sont recueillis, en premier lieu, dix semaines environ après la vaccination (premier contrôle). On examine par la suite à nouveau les enfants si possible six mois, un an, deux ans, et parfois trois et même cinq ans après la vaccination. Chaque contrôle porte d'une part sur les tests tuberculiniques, d'autre part sur la cicatrice de la lésion locale.

Une cause importante d'inégalité entre vaccins est représentée par l'origine de la souche. Les « souches-filles » qui dérivent de celle de Calmette ont assurément en commun beaucoup de caractères généraux. Mais elles sont loin de se comporter toutes de façon identique (voir notamment R. J. Dubos et coll., A. Frappier et M. Panisset, H. S. Willis et H. M. Vandiviere). Il en est d'assez « mordantes » et d'autres atténuées à l'extrême. À noter qu'aux « souches-filles » déjà cataloguées, il faut joindre maintenant les souches résistantes à l'isoniazide qui viennent d'entrer en scène.

Ce qui n'apparaît pas clairement à tous, est le rapport entre les caractères des souches-filles que l'on étudie au laboratoire et la valeur clinique des vaccins correspondants. Pourtant il n'est pas douteux qu'à une « virulence résiduelle » trop insignifiante corresponde un pouvoir protecteur diminué. Si on échoue parfois à la démontrer c'est faute d'employer les techniques appropriées.

Le degré d'atténuation de la « souche-fille » utilisée conditionne pour une large part l'activité des vaccins tels qu'on les emploie en clinique et les variations de la souche représentent un des plus grands obstacles à la standardisation du BCG. Soulignons qu'il n'est pas aisé d'apprécier exactement le rôle de ce facteur car les vaccins fabriqués à partir de sous-souches différentes viennent de laboratoires où les techniques de production diffèrent elles aussi.

La comparaison entre vaccins éprouvés à des dates espacées ne fournit donc pas des renseignements aussi précis que la confrontation entre lots étudiés le même jour. Cependant les données que nous avons recueillies en plusieurs années ont montré une régularité suffisante pour qu'il soit possible d'en tirer parti dans leur ensemble, l'exploitation statistique ayant fait apparaître celui-ci comme cohérent — [D. Schwartz et R. Orssaud].

L'analyse de la masse de nos résultats peut donc aider à aborder les questions sans doute les plus délicates que pose le contrôle d'activité du BCG : celles qui ont trait aux rapports des tests entre eux : une des plus grandes *difficultés* rencontrées tenant à la *nécessité de se fonder* à la fois sur les résultats de plusieurs épreuves, exprimant des caractères distincts quoique supposés tous en rapport avec les *propriétés immunisantes* du vaccin.

Les corrélations ne sont pas *très nombreuses* entre les tests cliniques et les tests de laboratoire. Bien entendu, on serait peut-être parvenu à mettre en évidence des corrélations supplémentaires en opérant dans *d'autres conditions* ou à une plus grande échelle. Mais il y a *toutes raisons* de croire que la méthode suivie a

permis de se manifester aux corrélations vraiment étroites

Schématiquement, on peut mettre à part les épreuves *in vitro* et classer les épreuves expérimentales et cliniques, selon leur signification en trois catégories, tests d'allergie tests de virulence tests de protection.

A. *Les comptes de colonies*

(a) *Significations des « nombres d'unités vivantes »* — Ils fournissent une donnée de base indispensable et permettent mieux que les seules mesures pondérales et photométriques, de définir la quantité de vaccin administrée à l'enfant Mais la valeur des chiffres qu'ils fournissent est limitée

On aurait tout-à-fait tort d'admettre que les vaccins les plus riches en unités vivantes sont nécessairement ceux qui protègent le mieux ou qui témoignent du plus grand pouvoir allergisant. Les constatations récentes de Willis et Vandivière sont, comme les nôtres, très démonstratives à cet égard.

(b) *Nécessité du recours aux techniques expérimentales et cliniques* Les comptes d'unités vivantes mis à part il serait tentant de s'appuyer sur d'autres techniques *in vitro* Malheureusement les tests métaboliques et enzymatiques décrits jusqu'à présent ne paraissent pas renseigner beaucoup sur l'efficacité du vaccin. Force est donc de se fonder davantage sur les épreuves expérimentales et cliniques que sur les résultats obtenus *in vitro*

B *Les tests d'allergie*

Ils sont les plus employés. Pratiqués au laboratoire chez le cobaye ils peuvent fournir des renseignements très précis et liés à ceux des tests tuberculiniques effectués chez l'enfant, comme on l'a signalé avant nous comme nous avons pu le vérifier Il y a lieu de mentionner à cet égard les corrélations partielles, à nombre d'unités vivantes constant, que nous avons décelées entre le diamètre du « Mantoux » au premier contrôle chez l'enfant et les résultats obtenus chez le cobaye

Rien n'indique cependant, que le pouvoir immunisant d'un vaccin soit nécessairement parallèle à son pouvoir allergisant.

Il n'y a donc pas à s'étonner que comme nous l'avons constaté il existe des vaccins, doués d'un pouvoir allergisant honorable qui protègent mal la souris. De tels faits incitent en dehors de toute prise de position doctrinale à refuser de voir dans la réponse des animaux ou des enfants aux tests d'allergie après vaccination une garantie suffisante de l'efficacité du vaccin employé

C *Les tests de virulence*

A notre sens il y a lieu d'accorder une place à ces tests qui, pour l'essentiel, traduisent la virulence du BCG Il y aurait lieu d'exiger que les vaccins témoignent chez le cobaye d'un minimum de virulence à en juger par la réaction locale corrigée

D *Les tests de protection*

C'est peut-être dans la difficulté d'arriver à un accord général sur la portée des tests d'allergie et de virulence que réside la meilleure justification du recours aux tests de protection. Le résultat de ceux-ci dépend certes, pour une part des capacités propres de réponse de l'espèce et même de l'individu Mais il traduit aussi les caractères propres du vaccin étudié et

renseigne ainsi sur son pouvoir immunisant.

Faute de pouvoir couramment recourir à des enquêtes cliniques de protection nous tendons à attribuer une valeur particulière aux tests expérimentaux de protection. Il y a assurément quelque arbitraire à juger d'après eux de l'efficacité d'un vaccin chez l'homme mais, dans l'état actuel des choses, on serait bien imprudent de se passer de la caution qu'ils apportent.

Conclusion

L'appréciation des vaccins BCG requiert l'emploi de plusieurs techniques expérimentales auxquelles s'ajoute utilement l'observation de groupes d'enfants vaccinés. La justification d'un tel effort résulte, avant tout, du risque d'efficacité insuffisante couru lorsqu'on vaccine avec un BCG d'activité trop faible. Il est donc proposé de soumettre les fabrications les plus diverses aux mêmes exigences minimales de pouvoir allergisant, de virulence résiduelle et de pouvoir protecteur expérimental. Le dispositif nécessaire même réduit à l'essentiel, demeurant assez lourd il n'est pas aisé de l'employer d'une manière tout-à-fait courante. Mais il pourrait servir par intervalles, au contrôle de chaque type de vaccin. Quant à la régularité de la production elle est appréciée par des comptes d'unités vivantes faites régulièrement.

bleau 2, où nous avons indiqué la moyenne des dosages effectués et, dans la parenthèse, les valeurs extrêmes. Pour le pH ce sont les valeurs maximales et minimales qui sont notées. Les différences sont particulièrement frappantes pour le pH, le potassium et le chlore; elles sont insignifiantes pour le calcium, le sodium et l'hémoglobine.

Le pH Théoriquement, la transfusion de sang citraté, dont le pH varie entre 6,4 et 6,7 (voir tableau 2) va causer une acidose métabolique par apport supplémentaire de ions H, acidose que les tampons de l'organisme et les régulations rénales et pulmonaires vont vraisemblablement tenter de compenser. Dans un deuxième temps, le citrate lui même sera métabolisé et transformé en bicarbonate, produisant ainsi une alcalose métabolique. Ces deux *phénomènes seront* d'autant plus nettement distincts l'un de l'autre que l'E.T aura été effectuée plus rapidement. Les différentes mesures effectuées sont résumées dans la figure 1, chaque ligne représentant les valeurs individuelles d'un seul sujet. Comme on pouvait le prévoir le pH baisse chez la plupart des nourrissons dès le début de l'E.T. Il se normalise spontanément par la suite et

Acides-bases et électrolytes au cours de l'exsanguino-transfusion à l'aide de sang citraté

*Communication préliminaire**

par G DUC et G DE MURALT

Les critiques formulées à l'égard de l'emploi de sang citraté pour l'exsanguino-transfusion (E. T) [8 9 14 15] nous ont incités à contrôler les variations de l'équilibre acide base et des électrolytes au cours de 25 échanges effectués chez des nouveaux nés hyperbilirubinémiques.

Matériel et méthode

5 nouveaux nés âgés de 1–189 heures ont fait l'objet de cette étude. Leur poids, leur âge respectif le diagnostic étiologique de l'hyperbilirubinémie sont indiqués dans le tableau 1 Aucun ne présentait de symptômes cliniques d'une affection respiratoire ou cardiaque

Les dosages suivants ont été effectués : pH (microméthode d'Astrup) sodium, potassium, chlore (méthode titrimétrique) calcium (méthode photométrique d'Eppendorf) hémoglobine (méthode à la cyanmethémoglobine) lactate et pyruvate (méthodes à la déhydrogénase lactique [11])

La pCO_2, le déficit ou l'excès de base ont été calculés à partir des valeurs du pH à l'aide du nomogramme de Siggaard Andersen [13]

Ces diverses mesures ont été effectuées :

(a) dans les flacons de sang utilisés après prélèvement du liquide citraté surnageant les érythrocytes sédimentés;

(b) chez tous les nourrissons avant l'E.T puis tous les 200 ml de sang transfusé et enfin 12 à 16 heures après la fin de l'E.T

Le pH a été déterminé dans le sang capillaire prélevé au talon après avoir trempé le pied pendant 10 minutes dans un bain d'eau à 40 degrés. Aucun des nourrissons n'ayant présenté de cyanose les corrections pour la désaturation n'ont pas été nécessaires.

Les dosages de sodium, potassium, chlore, calcium lactate et pyruvate ont été effectués dans le sang veineux prélevé par le cathéter ombilical, après avoir d'abord aspiré et jeté 10 ml de sang de façon à éviter toute contamination avec le mélange injecté

Le sang utilisé pour l'E T avait été prélevé au centre de Transfusion de la Croix Rouge Suisse à Berne chez des adultes sains. La solution anticoagulante ACD utilisée contient 0 47 % d'acide citrique 1 6 de citrate de sodium 2,5% de dextrose son pH est de 5 2.

100 ml d'ACD sont mélangés à 400 ml de sang

Résultats

La transfusion de sang citraté à un nouveau né va entraîner des modifications ioniques que les différences de composition entre le sang des donneurs et celui des nourrissons permettent de prédire Ces différences ont été résumées dans le ta

* L'article in extenso paraîtra plus tard.

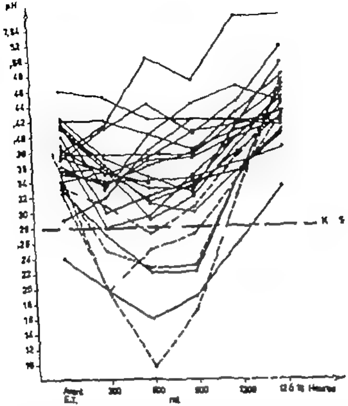

Fig. 1. Variations du pH au cours de l'E.T. Chaque ligne représente les valeurs individuelles d'un seul sujet. Tous les pH inférieurs à 7,28 (ligne horizontale) ont été mesurés chez des nouveau-nés âgés de moins de 12 heures au moment de l'E.T. Tous ces sujets ont présenté parallèlement à la baisse du pH, une élévation du potassium à des valeurs supérieures à 5 mEq/L. (K > 5, voir fig. 4).

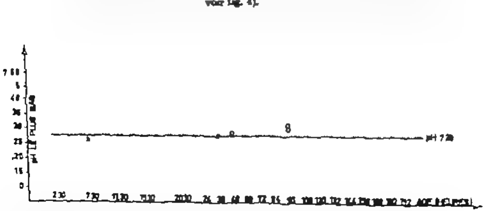

Fig. 2. Chaque cercle ou croix représente le pH le plus bas mesuré chez un sujet par rapport à son âge au moment de l'E.T. Tous les sujets, sauf un seul, âgés de moins de 12 heures au moment de l'E.T. ont présenté des pH inférieurs à 7,28.

TABLEAU 2. *Valeurs extrêmes du pH et moyennes des taux de potassium chlore, sodium calcium hémoglobine.*

Déterminations dans les 9 flacons de sang citraté (après prélèvement du liquide surnageant les érythrocytes sédimentés) et chez les nourrissons avant l'Ex.T Valeurs extrêmes dans la parenthèse

	Donneur (Citrat)	Nourrisson avant E.T
pH	6,4–6,7	7 24– 46
K mEq/L	7,3 (3 1–16,0)	4,3 (3, –5,1)
Cl mEq/L	63,3 (33–73)	117 (101–1*0)
Na mEq/L	14g (139–160)	143 (134–153)
Ca mgr %	8,0 (6,4–10,0)	9,0 (4,6–1_,8)
Hb gr %	16,4 (9 3–19,9)	14 8 (11 7–18,9)

atteint dans certains cas, des valeurs nettement alcalines comme on s y attendait également

L étude des variations simultanées du déficit de base et de la pCO_2 a montré que tous ces sujets présentaient dans un premier temps une acidose métabolique non compensée transformée ensuite en alcalose métabolique également non-compensée puisque la pCO_2 restait constante malgré la baisse importante du pH Ce fait a également été observé par Calladine et al [2] Ces diverses variations sont vraisemblablement sans importance biologique pour la plupart des sujets, car elles ne sont que de courte durée se normalisent spontanément et n atteignent pas des valeurs extrêmes. Pour six d entre eux cependant, c est l acidose qui est particulièrement frappante puisque les pH mesurés sont inférieurs à 7,23 et atteignent 7 10 même

L analyse détaillée des caractéristiques respectives de ces sujets a montré qu ils ne se distinguaient des autres ni par leur poids, ni par leur degré de maturation, ni par la rapidité avec laquelle l exsanguino transfusion avait été effectuée ni par le pH du sang des bouteilles utilisées. Un seul facteur commun à tous a pu etre retenu ces nourrissons étaient âgés de moins de 12 heures au moment de l échange.

Ce fait est illustré plus clairement dans la figure 2 où nous avons représenté la valeur la plus basse des pH mesurés chez un sujet par rapport à son âge au moment de l E T

Comme on peut le constater tous les nourrissons âgés de moins de 12 heures, à l exception d un seul ont présenté des pH inférieurs à 7,28 alors que chez les autres transfusés pourtant dans les mêmes conditions, le pH est resté supérieur à 7,28.

Ainsi il apparaît que l organisme dans les premières heures de la vie est moins à même de lutter contre l acidose métabolique imposée par la transfusion de sang citraté. On peut supposer que l immaturité des fonctions hépatiques (retard dans la métabolisation du citrate) et rénales (réponse tubulaire insuffisante à l acidification) sont à l origine de ce fait

Lactate et pyruvate

Le taux de lactate et de pyruvate varie entre 0,2 mMol/L et 5 mMol/L. Ces valeurs sont légèrement supérieures aux données de la littérature [6, 13]. Les sujets les plus jeunes présentaient les valeurs les plus hautes comme l ont déjà relevé d autres auteurs [13 16]. Durant l E.T le taux de lactate reste pratiquement constant Aucune corrélation n a pu être mise en

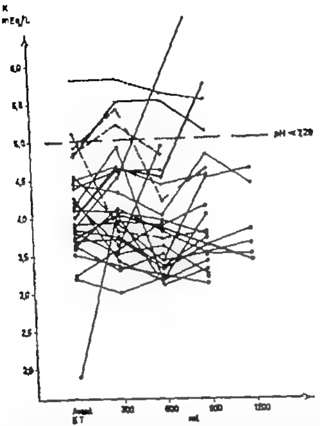

Fig. 4. Variations du K au cours de l'E.T. Chaque ligne représente les valeurs individuelles d'un seul sujet. Le sujet qui présente un K à 10,2 mEq/L à la fin de l'échange a reçu un flacon de sang contenant 16 mEq/L. Tous les autres sujets qui ont présenté de valeurs de K supérieures à 5 mEq/L avaient des pH < à 7,20 et étaient âgés de moins de 12 heures au moment de l'E.T (voir fig. 1).

Qu'en est-il en réalité?

Les variations du taux de potassium durant l'E.T. sont résumées dans la fig. 4. Pour la plupart des sujets, les fluctuations constatées sont vraisemblablement sans importance biologique, puisqu'elles restent dans les limites des normes. Pour six d'entre eux cependant, les valeurs sont supérieures à 5,0 mEq/L et s'élèvent même à 10,2 mEq/L dans un cas. Fait digne d'intérêt, cinq de ces sujets sont âgés de moins de 12 heures et ont présenté les pH les plus bas (fig. 2). Le nourrisson qui a présenté un taux de potassium à 10,2 mEq/L à la fin de l'échange était âgé de 18 heures, mais avait reçu à notre insu un flacon de sang contenant 16,0 mEq/L de potassium. Il n'a présenté aucun symptôme clinique. Il est à noter qu'un autre sujet, qui reçut un flacon de sang contenant 11,2 mEq/L n'a pas présenté d'hyperpotassémie.

Ainsi, tout comme pour le pH, l'hyperpotassémie constatée semble être en rap-

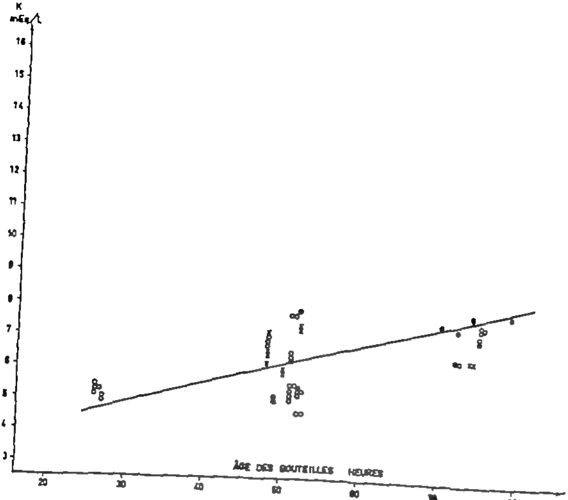

Fig. 3. K plasmatique dans l sang citraté « donneur » par rapport au temps écoulé après la prise de sang et son emploi pour l E.T

évidence entre la lactacidémie et les variations du pH

Le taux de pyruvate varie avant l E T entre 0,02 mMol/L et 0,20 mMol/L. Les variations du pyruvate sont sans rapport avec le pH

La dispersion des valeurs est en partie due aux difficultés de la méthode utilisée (déhydrogénase lactique : Richterich [11]) Ces résultats démontrent cependant que l acidose présentée par les nourrissons transfusés dans les premières 12 heures est sans rapport avec des variations du quotient lactate/pyruvate

Le potassium

Le taux de potassium plasmatique du sang citraté augmente progressivement dans les heures qui suivent la prise Ce fait a été relevé par d autres auteurs [4 7 10], nous l avons également vérifié (fig 3) Tous les flacons de sang utilisé plus de 70 heures après la prise contenaient plus de 6,4 mEq/L de potassium dans deux d entre eux ces valeurs s élevaient même à 11,2 mEq/L et 16,0 mEq/L.

Il est à prévoir que la transfusion d un tel sang à un nouveau né pourra entraîner une élévation de la potassémie

progressive durant tout l échange. Tout se passe comme si aucun mécanisme de contre-régulation ne tentait à s opposer à l'hypochlorémie que l'on impose à l orga nisme.

Ces perturbations sont sans rapport avec les variations du pH, du taux de potassium ou de sodium elles ne sont pas plus importantes chez les sujets transfusés dans les premières 12 heures.

Le sodium

Le taux de sodium dans les flacons de sang tilisé étant pratiquement le même que chez les nourrissons, on pouvait d avance prévoir qu il varierait peu au cours de l'E.T Ce fait a été vérifié.

Le calcium

Les variations du taux de calcium sont minimes u cours de l'E.T Tous nos sujets avaient reçu, comme il est coutume de le faire 1 ml de gluconate de calcium à 10 %. tous les 100 ml de sang transfusé. Ces résultats démontrent seulement que le taux de calcium total ne varie pas u cours de nos E.T

Il serait cependant erroné de conclure que le taux de calcium biologiquement actif (calcium ionisé) a été toujours suffi sant a cours de l'échange Notons cepen dant qu aucun sujet n a présenté de symptômes de tétanie.

Conclusions

L emploi de sang citraté pour l exsan guino-transfusion des nourrissons hyper bilirubinémiques, exempts d affections pulmonaires ou cardiaques, provoque une acidose métabolique non compensée avec hyperpotassémie chez les sujets âgés de moins de L heures. L acidose métabolique fait place à une alcalose métabolique non compensée dans les 1 à 16 heures qui suivent l échange

D autre part chez tous les sujets le taux de chlore baisse progressivement au cours de l échange alors que le sodium et le calcium restent inchangés. Ces différentes variations ne s accompagnant d aucun symptôme clinique et se normalisant spon tanément, il nous parait injustifié d aban donner systématiquement l emploi du sang citraté pour recourir au sang héparmé

Les précautions suivantes sont à con seiller

1 Le liquide surnageant les érythrocytes sédimentés sera prélevé avant l échange de façon à diminuer autant que possible l apport d'ions H.
2. Le sang des donneurs ne doit être utilisé que moins de 48 heures après la prise de sang, de façon à éviter l'hyperpotassémie.
3. L exsanguino-transfusion doit être f fectuée particulièrement lentement (moins de 5 ml/kg/min) chez les sujets âgés de moins de 12 heures, chez lesquels d autre part il est à conseiller de déterminer au cours de l échange, le pH.
4. Toute acidose métabolique durable sera corrigée à l aide de bicarbonate par voie intraveineuse. La quantité de bicarbonate à injecter dépendra du pH

Des études complémentaires sont en cours pour déterminer si l emploi systématique de bicarbonate ou de Tris doit être recommandé.

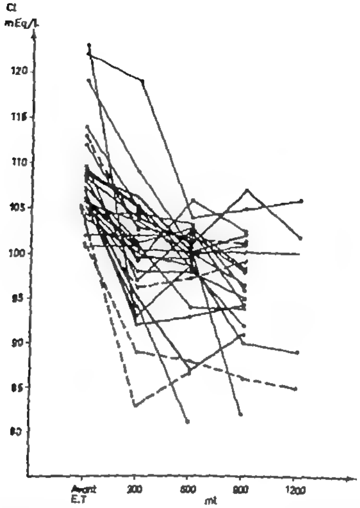

Fig 5. Variations du Cl au cours de l'E.T Chaque ligne représente les valeurs individuelles d un seul sujet. La chlorémie baisse progressivement au cours d l E.T Les sujets âgés de moins de 12 heures au moment de l'E.T (lignes épaisses ou tratillées) ne se distinguent pas des autres.

port étroit avec l âge du nourrisson au moment de l E.T , puisque les sujets plus âgés, qui avaient pourtant été transfusés avec des flacons de sang contenant des taux de potassium analogues n ont pas présenté d hyperpotassémie

L augmentation du potassium plasmatique chez les sujets âgés de moins de 12 heures est vraisemblablement en rapport avec l acidose métabolique qu ils ont présentée, la baisse du pH provoquant une fuite du potassium intra-cellulaire dans le plasma. Ce phénomène a été démontré in vitro par Fenn et Cobb [3], et in vivo chez l animal par Keating *et al* [6], chez l'homme par Burnell *et al.* [1]

Le Chlore

L'hypochlorémie constatée dans tous les flacons de sang (tableau 2) va provoquer vraisemblablement un abaissement du taux de chlore chez les nourrissons Ce fait a été constaté dans tous les cas (fig 5) La baisse du taux de chlore est d autant plus importante que la chlorémie était plus basse au départ, cette baisse est

Acta Paediatrica Scandinavica Supplement 172, 1967

From the Children's Hospital and the University Sheffield, England

Evidence from Bone Growth that Most of the Infants Dying in the Neonatal Period had been Ill Before Birth

by JOHN L. EMERY

The subject that I have chosen for inclusion in this volume in honour of Professor Constantin Choremis arises from our very first conversation. When, nearly ten years ago, my old colleague and friend Spiros Doxiadis first introduced me to Constantin Choremis, he asked me to speak to his unit. I did so on some problems of bone growth in the foetus.

It was in private conversation following this that I began to realise the wide and philosophical under-current that lay behind Choremis's remarks and it was then that I first began to appreciate the hidden depths of this unusual man, a man to whom the growth of the trees in his garden, the growth of bones, and the growth of ideas were as one thought.

Greece has long been the classic site of the study both of philosophy and of archeology and the investigations discussed here are essentially the employment of an archeological concept, an attempt to read into the pattern of structure of the newborn bones, the previous history of the child. We in Sheffield have also been particularly fortunate in being associated in this work by a paediatrician pupil of the Athens school of Medicine, Pitsa Kalpaktsoglou.

The period after the 1914-18 European war was the time when the pathology of rickets, scurvy and the great deficiency diseases of childhood was largely worked out by Follis and Park in the United States [1, 2, 3, 4]. There was also the fascinating correlation of the radiological findings in bone of lines of growth arrest described by Harris [5]. This work is summarised in a magnificent way by Park in 1964 in his Goldberg Lecture [4]. He shows how postnatal general and nutritional diseases leave lasting effects on the structure of the bones of the child. That work concerned childhood and those who worked on the osseochondral junctions of children dying in the newborn period, simply remarked that these, too, showed the changes of rickets.

Approximately fifteen years ago we first started using the results of Park's study as a means of assessing the previous health of children who had been found unexpectedly dead (the so-called 'cot deaths') and, having found this to be extremely useful [6], went on to attempt to apply the same principals to perinatal deaths.

Most clinical work on bone has been done on the lower end of the femur and

Evidence from Bone Growth that Most of the Infants Dying in the Neonatal Period had been Ill Before Birth

by JOHN L. EMERY

The subject that I have chosen for inclusion in this volume in honour of Professor Constantin Choremis arises from our very first conversation. When, nearly ten years ago, my old colleague and friend Spyros Doxiadis first introduced me to Constantin Choremis, he asked me to speak to his unit. I did so on some problems of bone growth in the foetus.

It was in private conversation following this that I began to realise the wide and philosophical under-current that lay behind Choremis's remarks and it was then that I first began to appreciate the hidden depths of this unusual man; a man to whom the growth of the trees in his garden, the growth of bones, and the growth of ideas were as one thought.

Greece has long been the classic site of the study both of philosophy and of archeology and the investigations discussed here are essentially the employment of an archeological concept, an attempt to read into the pattern of structure of the new born bones, the previous history of the child. We in Sheffield have also been particularly fortunate in being associated in this work by a paediatrician pupil of the Athens school of Medicine, Pitsa Kalpaktsoglou.

The period after the 1914–18 European war was the time when the pathology of rickets, scurvy and the great deficiency diseases of childhood was largely worked out by Follis and Park in the United States [1, 2, 3, 4]. There was also the fascinating correlation of the radiological findings in bone and lines of growth arrest described by Harris [5]. This work is summarised in a magnificent way by Park in 1964 in his *Goldberg Lecture* [4]. He shows how postnatal general and nutritional diseases leave lasting effects on the structure of the bones of the child. That work concerned childhood and those who worked on the osteochondral junctions of children dying in the newborn period, simply remarked that these, too showed the changes of "rickets".

Approximately fifteen years ago, we first started using the results of Park's study as a means of assessing the previous health of children who had been found unexpectedly dead (the so-called "cot deaths") and, having found this to be extremely useful [6], went on to attempt to apply the same principals to perinatal deaths.

TABLE 1 *The major criteria for the assessment of the costochondral junction.*

	Criteria for grouping the ribs		
	Normal	Simple growth retardation	Bizarre growth
Junctional line	Distinct	Very definite	Indistinct
Cartilage columns	Cells in straight, single or double columns—simple/compound, straight	*Cells in straight single or double columns—simple/compound, straight*	*Irregular compound, complex with many cells in irregular clusters*
Thickness of Zone I, the layer of swollen cartilage cells in columns	0.03–0.04 mm	Diminished	Increased or normal
Thickness of Zone II, the layer of cartilage cells between the resting cells and the swollen ones above	0.06–0.09 mm	Normal or diminished	Very variable
Bridging of matrix across the ends of the cartilage cells	Minimal	Present	Present
Bandings of matrix left behind in the bone	Absent	Present	Present
Matrix pools, masses of cartilage matrix reaching the bone	Few	Variable	Many irregular

reached and each column of cells leaves behind at its side, a thin film of matrix (Fig. 1).

If for any reason, there is a diminution in the rate of growth, the 'firing' rate of the cells diminishes and two things become rapidly obvious. First, there is a thickening and irregularity of the strands between the cartilage columns and second if at any *time* the *actual discharge* of cells ceases, then a thin cap of matrix occurs between the terminal cartilage cell and the marrow cavity. If this process continues for any length of time a cross-banding of matrix occurs (Fig. 1*b*) often over-capping several cartilage cell columns. At the same time the marrow cavity continues to absorb the trabeculae so that there is bridging of trabeculae over groups of cartilage columns.

When the rate of growth is intermittent, the cartilage cells proliferate behind these bands *and bridges and the latter are left* behind within the bone as a series of tide-marks which correspond at a microscopic level to the calcified cross-striation in bone known clinically as Harris's lines. These cross bands cannot be shown on an x ray plate both because of their size and because they are not usually deeply calcified. In practice, this type of lesion can very frequently be found.

When there has been disturbance of growth over a continuous period with incomplete cessation of growth, the whole costochondral junction loses its general regular form, the bands of matrix that are left behind in the bone are similarly irregular and the cartilage columns lose their direct longitudinal orientation. This is a picture which we describe as bizarre [7] (Fig. 1*c*). It has some superficial resem-

Fig 1 Photographs of costochondral junctions from three children, all perinatal deaths. (a) A normal junction Note the long rows of cartilage cells leading off directly into the bone with long thin strands of trabeculae matrix. (b) A junction showing a period of growth retardation. Note the great increase in the amount of cartilage matrix and the building up of this matrix between the cartilage cells and the bone marrow (c) A junction showing a bizarre picture. The general junction line is not obvious and there are irregular masses of matrix. The marrow blood vessels are also penetrating in an irregular manner and the cartilage cells occur in large irregular nests.

the head of the radius, largely because these bones are most easily available for x ray studies, but, for doing microscopic studies, the rib is much better as it is probably the most rapidly growing long bone and it grows in a linear fashion throughout almost the whole of intra uterine life The more rapid the basic growth rate of a tissue the more obvious and early are the effects of growth arrest

The costochondral junction normally appears as a series of columns of cartilage cells between strands of cartilaginous matrix and these strands continue on into the bony trabeculae. This has a rather rigid and static appearance

The costochondral junction, however is an extremely active structure. A fully distended cartilage cell is about 14 μ thick. When the size of the cartilage cells is taken into consideration together with the increasing length of the bone (0 43 mm or 430 μ a day) we find that at least the length of a whole column of the ballooned cartilage cells must be replaced every day If we were able to look at the living costochondral junction the actual blowing up of the small cartilage cells into the large, ballooned cells is so rapid that it could almost be seen occurring The costochondral junction is thus not a static structure at all, but much more like a series of small rockets or a sort of slow firing multi barrelled jet, the cartilage cells distend and burst into the cartilage cavity so that the cartilage recedes from the shaft leaving a slip-stream of matrix behind.

In the fixed section of the normal costochondral junction, the marrow ends of these rockets (columns of cartilage cells) are open. There is a progressive increase in size of the cells as the marrow cavity is

TABLE 1 *The major criteria for the assessment of the costochondral junction.*

reached and each column of cells leaves behind at its side, a thin film of matrix (Fig. 1a).

If for any reason, there is a diminution in the rate of growth, the "firing" rate of the cells diminishes and two things become rapidly obvious. First, there is a thickening and irregularity of the strands between the cartilage columns and second if at any time the actual discharge of cells ceases, then a thin cap of matrix occurs between the terminal cartilage cell and the marrow cavity. If this process continues for any length of time a cross-banding of matrix occurs (Fig. 1b), often over-capping several cartilage cell columns. At the same time the marrow cavity continues to absorb the trabeculae so that there is bridging of trabeculae over groups of cartilage columns.

When the rate of growth is intermittent, the cartilage cells proliferate behind these bands and bridges and the latter are left behind within the bone as a series of tide-marks which correspond at a microscopic level to the calcified cross-striation in bone known clinically as Harris's lines. These cross bands cannot be shown on an x ray plate both because of their size and because they are not usually deeply calcified. In practice, this type of lesion can very frequently be found.

When there has been disturbance of growth over a continuous period with incomplete cessation of growth, the whole costochondral junction loses its general regular form the bands of matrix that are left behind in the bone are similarly irregular and the cartilage columns lose their direct longitudinal orientation. This is a picture which we describe as bizarre (7) (Fig. 1c). It has some superficial resem-

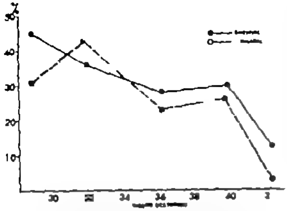

Fig. — The perinatal child deaths have here been grouped on gestational age at birth, based on the last menstrual period. The proportion of rib ends that appear to be within normal limits are recorded for the Sheffield series and for those available from the rest of the United Kingdom through the Perinatal Mortality Survey

blance to the changes seen in rickets during infancy and it is this picture which undoubtedly led the early workers to consider that the normal costochondral junction of the newborn showed the changes of rickets. The criteria for assessment of the ribs are shown in Table I. These changes in the growing ribs seen in neonates correspond very closely with those described in older children by other workers [8].

Material Studied

We have done histological examinations on the ribs of every child coming to necropsy for the past fifteen years and our observations are thus based upon examination of the costochondral junction of the ribs of over 4,000 children, over 2,000 of which died in the perinatal period. The details of handling the ribs and assessment and measurement are described elsewhere [7].

The assessment of normal structure is one of the most difficult in pathology of the newborn period. Since we have very frequently seen obvious signs of intrauterine disease, such as fatty liver, in children who have apparently died from trauma to the brain during delivery, we have been extremely strict in our criteria for assessing normals. The only ribs that we have accepted as being normal have come either from children who have died immediately *in utero* as a result of a pregnant woman being involved in a road accident, or from children dying during labour as a result of vasa previa. We have not accepted placenta previa.

Results of Recent Survey of 1 064 Perinatal Deaths

Kalpaktsoglou and I recently made a definitive study of ribs from a series of 1 064 perinatal deaths. The cases came from two groups of children, 684 consecutive cases from the files of the Children's Hospital in Sheffield and 380 coming from children who had come to necropsy during the recent Mortality Survey [9] carried out in England in 1961 and in which the pathologists had kindly sent me the ribs of all their cases dying during the selected month. We had, thus, our own fairly large series and a smaller, almost random group from the whole of the rest of the United Kingdom.

Of the total of 1 064 ribs, 332 only could be considered as within the range of normal and 732 showed what we considered to be definite changes indicating that the child had been ill and not growing for at least a week prior to the onset of labour.

The full details of the cases and results are presented elsewhere [ ]. The results were analysed in a variety of ways including gestation age, body length and history.

When we studied our findings from the point of view of the proportion of deaths at different gestational age showing no significant rib growth disturbance, we found that the instances of lesion in the Sheffield series coincided almost exactly with those obtained from ribs of children

dying elsewhere (Fig 2). The trend of both these series is quite distinct and statistically valid. The gestational age at which the highest proportion showed no evidence of intrauterine disease was less than 32 weeks when the proportion was around 40%. As the deaths occurred at later gestational ages, the proportion of children with normal ribs diminished progressively so that around full term, the proportion was only bout 25% and this figure reached 6% only in one group of children dying after prolonged gestation (42+ weeks)

If these assessments are correct, the implications appear to be that in the perinatal period, the great majority of deaths occur in infants that have been ill long before the onset of labour and that this applies mostly to the children born around term. This does not mean necessarily that birth trauma or other stresses of labour had no part in these children's deaths, for in children already ill, the "normal trauma of birth would be of greatly increased importance. It would seem to imply however that if we are to further diminish perinatal mortality we must look with greater concentration at the foetus during later pregnancy for evidence of diminution in growth rate or of some chemical indication of intrauterine athrepsia in order to shield these infants during labour or induce labour while the child is fit enough to stand its stress.

Summary

A survey of the pattern of growth, as revealed by the structure of the costochondral junction, suggests that the great majority of infants dying in the neonatal period had intrauterine disease antedating labour This involves approximately 90% of premature birth deaths and around 75% of perinatal deaths at term.

The Differentiation and Maturation of Specific Immune Mechanisms

by DAVID GITLIN

The capacity of the mature individual to repel the hostile incursions of infectious organisms is dependent upon the complex interaction of a number of different factors, each of which to be entirely effective as part of the defense system must operate for the most part in unison with the others. The factors involved may be specific in that they have a selective action against only a specific agent or against a small group of structurally similar agents, or they may be nonspecific in that they are directed against relatively large groups of different organisms. The specific factors of immunity are of course the antibodies, since an antibody may be defined as any substance which is synthesized by the body in response to antigenic stimulation and which will react specifically or almost exclusively with that antigen. Nonspecific factors include such obvious physical barriers as the skin and mucous membranes proteins such as lysozyme and interferon, and cell populations such as the granulocytes and the reticuloendothelial system Some of the nonspecific factors have limited effectiveness independently of the specific factors, but most perform more efficiently when specific antibodies are also present, and some are entirely dependent upon antibodies for effective action. On the other hand, antibodies alone have little or no direct lethal action against the bacteria and some viruses at least and for bactericidal activity specific antibodies require the coordinated intercession of such nonspecific factors as the granulocytes, the reticuloendothelial system or complement It is clear then that a deficiency of but a single factor in the immune system may result in a partial or complete failure of the defense Since most of these factors, both specific and nonspecific differentiate at different stages of fetal and neonatal development and mature at different rates one from the other one or more immune factors will be deficient or absent at any given time during early development Thus, in the period between early intrauterine life and early childhood, the ability of the individual to resist infection changes dramatically It is the purpose of this discussion to describe the differentiation and maturation of specific immunological factors and to relate these factors to immunity against infection.

It is almost unnecessary to state that all antibodies are of intracellular origin. Some cells synthesize antibodies and release them into the plasma as free proteins

known as immunoglobulins; still other cells synthesize antibodies which remain, for the most part at least, as an integral part of the cell. The latter type antibodies, often referred to as cellular antibodies, are synthesized primarily in small lymphocytes; the immunoglobulins are synthesized by plasma cells and related lymphocytoid cells. A deficiency in antibody synthesis, therefore, theoretically may result either from a deficiency or absence of those cells responsible for antibody synthesis, or from a deficiency or suppression of any of the antibody synthesizing steps from DNA coding of messenger RNA to final antibody release either from the cell or from the ribosome.

The Immunoglobulins

Structure. The immunoglobulins of plasma migrate electrophoretically as γ_1 and/or γ_2-globulins; for the present at least, they have been classified into five major classes or groups. Each of these immunoglobulin groups has, over the years, acquired a number of different names as each investigator categorized the newly discovered proteins according to different systems of protein classification. To obtain some degree of uniformity in nomenclature still another system of classification was recently adopted by a conclave of workers in this field and this system is sometimes referred to as the WHO nomenclature [1]. Although all of the previously recorded names of each of the immunoglobulins admittedly have equal validity the latter nomenclature will be used here and the reader is referred to Table 1 for the older and perhaps more familiar designations.

Three immunoglobulin classes, γG (IgG) γA (IgA), and γM (IgM) together account for over 99% of all the plasma γ-globulins and thus represent the bulk of the total plasma antibodies (Table 1). The remaining relatively small amount of immunoglobulins includes γD (IgD) [2] and a group of γ-globulins of relatively low molecular weight [3, 4]. The γG immunoglobulins are primarily γ_2-globulins on electrophoresis, while γA, γM and γD are γ_1 globulins. The low molecular weight γ-globulins represent both γ_1 and γ_2-globulins. Each immunoglobulin molecule with the exception of the low molecular weight γ-globulins consists of equal numbers of two quite different polypeptide chains, the light chains and the heavy chains; the low molecular weight plasma γ-globulins are composed only of structures immunologically related to the light chains and lack heavy chains. The light chains in each immunoglobulin class are similar to those found in each of the other classes [5–7] and can be differentiated into two types which differ markedly in peptide structure: the κ-chains and the λ-chains [8–10]. On the other hand, the heavy chain in each immunoglobulin class is characteristic of that class and differs from the heavy chains of each of the other immunoglobulin classes: the heavy chains of γG have been designated γ-chains while those of γA, γM and γD are termed α-chains, μ-chains and δ-chains, respectively [1]. The light and heavy chains are held together in the molecule by means of disulfide bonds, the heavy chains imparting the structures responsible for much of the antibody activity although maximum antibody activity requires light chains as well as heavy chains [11–13]. A given

TABLE 1 *Plasma immunoglobulins Metabolic rates*

WHO nomenclature	Earlier names	Molecular weight	Plasma concentration mg/100 ml	Plasma concentration µmoles/100 ml	Half life (days)	Synthesis mg/kg/day	Synthesis µmoles/kg/day
γG or IgG	γ, γ_2, γSS, 6.6Sγ, 7S γ	±155 000	1 000 (600–1800)	6	25	28	0.17
γA or IgA	β_2A, γ_1A, 7S–14S γ	±155,000 (400,000)	90 (30–100)	0.5	7	7–11	0.04–0.07
γM or IgM	γ_1 macroglobulin, β_2M, γ_1M, 19S γ	±800,000	80 (50–100)	0.1	10	5–8	0.006–0.01
γD or IgD	γ_1D	±155,000	3 (0.3–40)	0.2	—	—	—
$\gamma_{K,L}$	Low molecular weight	±15,000	0.1	0.007	0.4	0.18	0.01

γ-globulin molecule may contain either κ chains or λ-chains, but not both; those molecules which have κ chains are said to be type K molecules and those with λ-chains are type L molecules. Both type K and type L molecules are usually found in the same person.

To recapitulate, the γ-globulins are at present divided into five different groups on the basis of differences in heavy chain composition and each of these classes can be further divided into type K or type L molecules depending upon the light chains in the molecule. The molecular structure of γG therefore may be written as $\kappa_2\gamma_2$ or $\lambda_2\gamma_2$. γG has a molecular weight of approximately 155 000 and the individual isolated light and heavy chain units have weights of 20 000 and 55 000 respectively [11–14]. Similarly γA, γM and γD have the following structures, respectively: $(\kappa_2\alpha_2)_n$ or $(\lambda_2\alpha_2)_n$; $(\kappa_2\mu_2)_n$ or $(\lambda_2\mu_2)_n$; and $\kappa_2\delta_2$ or $\lambda_2\delta_2$. For most of the γA in plasma $n = 1$ and the molecular weight is similar to that of γG, but some of the molecules of γA have higher molecular weights and for these n may be 2, 3 or 4. The molecular weight of γM is approximately 800 000 to 1 000 000 so that n in the structural formula is either 5 or 6.

But the heterogeneity in γ globulin structure is far more complex than is indicated by their separation in five major divisions or even ten subclasses. And even the less obvious structural modifications are more than simply of academic interest, since as will be shown, these variations relate to differences in function and metabolism and, consequently, have clinical significance. The κ chains can be divided into subgroups on the basis of structural differences designated as Inv groups [15, 16] and the heavy chains may differ in structural components called the Gm groups [17, 18]. There are at least two different Inv groups and at least seven or eight different Gm groups known, all of which are genetically determined and modify the structure of the γ globulin molecule. A person homozygous for a given Gm allele can nevertheless synthesize some γ globulin molecules lacking that

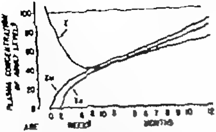

Fig. 1 The relative changes in the plasma concentrations of γG, γA and γM with age. The abscissa changes coordinates to months after 10 weeks of age.

specific Gm structure to add to the complexity. There are at least four genetically determined variations in the γ-chain structure of γG which have been identified in addition to those already mentioned, two of them being related to specific Gm groups [19]. And there is evidence to indicate that a specific antibody activity is related to the primary structure of the γ-globulin molecule so that each specific γ-globulin antibody differs in fundamental structure from all other γ-globulin molecules having a different antibody specificity [20–22].

The γ-globulins found in plasma are not the only immunoglobulins present in the body fluids. To the contrary normal urine, saliva and colostrum at least, and probably the bronchial secretions as well, contain γ-globulins *not found in plasma* as well as some of those present in plasma. At least four immunoglobulins which are similar in structure to each other have an average molecular weight of 12 000 and thermoprecipitation properties like those of Bence Jones proteins are found in normal urine, but in small amounts [4 23–26]. Unlike plasma, the immunoglobulins in saliva and colostrum are primarily γ-globulins, most of which are different from those in plasma. In saliva, the predominant γ-globulin is one related to but different structurally from plasma γA [27] and colostrum contains not only a unique γA but also a γ globulin related to, but different from, plasma γG [28]. It is important to note that in such body fluids, the function of a given plasma γ-globulin such as virus neutralization which is normally a property of plasma γG may be assumed by the unique γ-globulin of the excretory organ, such as the γA of saliva or colostrum or the low molecular weight urine γ-globulins.

Normal maturation of immunoglobulin metabolism. The plasma concentration of γG in the normal adult is approximately 600 to 1,000 mg %. The antibodies found in γG include those which neutralize bacterial exotoxins and viruses and those which promote phagocytosis of bacteria. But the protection afforded by γG depends not only upon the antigenic experience of the individual, each exposure having the potential of stimulating the production of specific γG antibodies, but also the maturation of the γG synthesizing mechanisms. Although the human fetus has the capacity to synthesize detectable amounts of γG beginning by the sixth or seventh month of gestation, the amount synthesized is quite small, reaching only 0.1 to 1% of that in the adult per kilogram of body weight at the time of birth [29 30]. Yet, the normal infant at birth has a plasma concentration of γG which frequently exceeds that of the mother. Virtually all of the γG found in the full term new born is obtained from the plasma of the mother by transfer across the placenta [31 32]. This transfer is highly selective, since it is

not related to the molecular size of γG [31–33] and the permeability of the near term placenta for γG seems to be greater in the direction of mother to fetus than it is in the direction of fetus to mother [32] Many smaller proteins such as albumin which has a molecular weight of 65 000 orosomucoid with a molecular weight of 44 000 or pituitary growth hormone of molecular weight 35 000 do not traverse the term placenta nearly as readily as does γG [31] But the permeability of the placenta to γG is quite different at different stages of gestation. at six to seven weeks gestation, the fetal plasma γG concentration is but 50 to 100 mg and as late as 22 to 24 weeks gestation, it is only 100 to 200 mg% yet by 28 to 30 weeks of gestation the plasma concentration is only slightly lower than that at term indicating a relatively sudden selective increase in placental permeability to γG during the last part of the sixth and the early part of the seventh month of pregnancy [34] Beginning immediately after birth the plasma γG concentration falls with a half life of approximately one month (Figs. 1 and 2) since γG is catabolized like other proteins and synthesis by the newborn infant is quantitatively relatively insignificant The level of γG continues to fall until, by one to three months of age the rate of synthesis has increased to the point where the amount of γG synthesized becomes equal to the amount being degraded (Fig 2) and the plasma γG level stops falling [35] at this point the plasma γG concentration is approximately 300 to 000 mg%, being partly of maternal origin and in part of endogenous origin. Synthesis by the infant increases with time and the plasma γG

concentration rises until by one to t years of age the child has a concentratı of γG comparable to that in the adult

It should be clear that the protectı afforded by γG in the newborn infan whether full term or prematurely bor is dictated by the nature of the antibodı present in the mother Thus, if the mothe has γG antibodies against diphtheria toxı or against measles, the infant born at ı time after seven months gestation wıl have concentrations of these antibodie approximately equal to those in the maternal circulation. After birth these maternally derived antibodies will be degraded with a half life of about one month as was noted for the total plasma γG If in a hypothetical instance a mother had a plasma concentration of γG anti measles antibodies which in an otherwise nonimmune person was 32 times that necessary to confer passive immunity the infant

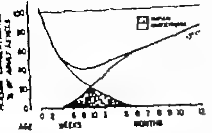

Fig. 2. The change in plasma γG concentration during the first year of life as the net balance between degradation of γG obtained from the mother and the synthesis of γG by the infant.

at birth would have a similar titer by one month of age, however the specific γG antibody titer would fall to half that present at birth and in each succeeding month, the titer would fall to half that in the preceding month, by five months of age, the titer would be approximately 1/32 that at birth or just enough to confer protection, but after five months of age the amount of anti-measles antibody left would be too low for adequate passive immunity. On the other hand, if the mother had anti-measles antibodies in a concentration just adequate to confer passive immunity the infant of that mother would have little γG protection against measles soon after birth despite the presence of almost adult γG concentrations. An infant passively protected against measles with γG may still acquire the infection when exposed to the virus, but clinical symptoms may not be evident and the infection may stimulate endogenous antibody synthesis, under such circumstances, passive immunity is converted to active immunity against measles. Thus, in the infant protected against measles during the first months of life by transfer of maternal γG *in utero*, exposure to measles during the passive immune period can lead to permanent immunity without clinical measles appearing at any time. Since the infant does not synthesize significant quantities of γG until one to three months of age specific γG antibody synthesis occurs primarily after one to three months of age but the amount of specific antibody needed for protection against measles is so small, that theoretically at least, even the small amount of γG synthesized by the infant before one month of age, can, with proper stimulation, have sufficient measles antibody to offer significant protection.

The infant at birth normally has little or no γM, yet the human fetus can, and does when stimulated antigenically synthesize specific γM antibodies beginning as early perhaps as three to four months gestation. By the time of birth, a relatively large proportion of the γM synthesizing capacity is operative but still inactive. With birth, and stimulation from the environment, γM synthesis rises rapidly (Fig. 1) the plasma γM concentrations reaching half of adult levels by three months of age [16, 27].

Antibodies which are γM proteins do not readily traverse the placenta at any time during pregnancy. Since most of the bactericidal activity of plasma against Gram-negative bacilli is due to specific γM antibodies acting in conjunction with complement, the deficiency of γM in the infant at birth represents a concomitant deficiency of such bactericidal antibodies [38]. This may have a significant bearing on the marked susceptibility of the infant to serious infections with Gram negative bacilli during the newborn period. Some mothers, due to repeated antigenic stimulation, can synthesize a small fraction of

not related to the molecular size of γG [31–33] and the permeability of the near term placenta for γG seems to be greater in the direction of mother to fetus than it is in the direction of fetus to mother [32] Many smaller proteins such as albumin which has a molecular weight of 65 000 orosomucoid with a molecular weight of 44 000 or pituitary growth hormone of molecular weight 35 000 do not traverse the term placenta nearly as readily as does γG [31] But the permeability of the placenta to γG is quite different at different stages of gestation. at six to seven weeks gestation the fetal plasma γG concentration is but 50 to 100 mg and as late as 22 to 24 weeks gestation, it is only 100 to 200 mg %, yet by 28 to 30 weeks of gestation, the plasma concentration is only slightly lower than that at term indicating a relatively sudden selective increase in placental permeability to γG during the last part of the sixth and the early part of the seventh month of pregnancy [34] Beginning immediately after birth the plasma γG concentration falls with a half life of approximately one month (Figs. 1 and 2) since γG is catabolized, like other proteins, and synthesis by the newborn infant is quantitatively relatively insignificant The level of γG continues to fall until, by one to three months of age the rate of synthesis has increased to the point where the amount of γG synthesized becomes equal to the amount being degraded (Fig 2) and the plasma γG level stops falling [35] at this point the plasma γG concentration is approximately 300 to 600 mg % being partly of maternal origin and in part of endogenous origin. Synthesis by the infant increases with time and the plasma γG concentration rises until by one to two years of age the child has a concentration of γG comparable to that in the adult.

It should be clear that the protection afforded by γG in the newborn infant, whether full term or prematurely born is dictated by the nature of the antibodies present in the mother Thus, if the mother has γG antibodies against diphtheria toxin or against measles the infant born at a time after seven months gestation will have concentrations of these antibodies approximately equal to those in the maternal circulation. After birth these maternally derived antibodies will be degraded with a half life of about one month as was noted for the total plasma γG If in a hypothetical instance a mother had a plasma concentration of γG anti measles antibodies which in an otherwise non immune person was 32 times that necessary to confer passive immunity the infant

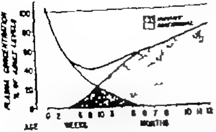

Fig. 2. The change in plasma γG concentration during the first year of life as the net balance between degradation of γG obtained from the mother and the synthesis of γG by the infant.

at birth would have a similar titer by one month of age however the specific γG antibody titer would fall to half that present at birth and in each succeeding month, the titer would fall to half that in the preceding month, by five months of age, the titer would be approximately 1/32 that at birth or just enough to confer protection, but after five months of age, the amount of anti-measles antibody left would be too low for adequate passive immunity On the other hand, if the mother had anti-measles antibodies in a concentration just adequate to confer passive immunity the infant of that mother would have little γG protection against measles soon after birth despite the presence of almost adult γG concentrations. An infant passively protected against measles with γG may still acquire the infection when exposed to the virus, but clinical symptoms may not be evident and the infection may stimulate endogenous antibody synthesis; under such circumstances, passive immunity is converted to active immunity against measles. Thus, in the infant protected against measles during the first months of life by transfer of maternal γG a *stero* exposure to measles during the passive immune period can lead to permanent immunity without clinical measles appearing at any time. Since the infant does not synthesize significant quantities of γG until one to three months of age specific γG antibody synthesis occurs primarily after one to three months of age; *but the amount of* specific antibody needed for protection against measles is so small, that theoretically at least, even the small amount of γG synthesized by the infant before one month of age, can, with proper stimulation, have sufficient measles antibody to offer significant protection.

The infant at birth normally has little or no γM, yet the human fetus can, and does when stimulated antigenically synthesize specific γM antibodies beginning as early perhaps as three to four months gestation. By the time of birth, a relatively large proportion of the γM synthesizing capacity is operative but still inactive. With birth and stimulation from the environment, γM synthesis rises rapidly (Fig 1) the plasma γM concentrations reaching half of adult levels by three months of age [36, 37].

Antibodies which are γM proteins do not readily traverse the placenta at any time during pregnancy Since most of the bactericidal activity of plasma against Gram-negative bacilli is due to specific γM antibodies acting in conjunction with complement, the deficiency of γM in the infant at birth represents a concomitant deficiency of such bactericidal antibodies [38]. This may have a significant bearing on the marked susceptibility of the infant to serious infections with *Gram-negative* bacilli during the newborn period. Some mothers, due to repeated antigenic stimulation, can synthesize a small fraction of

the total plasma bactericidal antibodies as γG the latter of course can traverse the placenta and under these conditions the infant is born with a small amount of γG bactericidal antibodies. But although many γG antibodies against Gram negative bacilli can be detected in maternal serum by hemagglutination and other related tests, and hence can be found in the newborn s plasma as well such antibodies have little or no bactericidal activity against the same organisms *in vitro* On the other hand the failure of transplacental transfer of γM can have certain beneficial aspects the α and β-isohemagglutinins present in normal plasma are primarily of the so-called natural or saline-precipitating type and these are γM proteins such maternal antibodies regardless of titer do not readily cross the placenta to affect a fetus whose ABO type is incompatible with that of the mother [39] Since some anti Rh antibodies are γM proteins, the maternal anti Rh titer alone is not necessarily an adequate guide to the amount of antibody passing to the fetus [39] Those hemagglutinins which do traverse the placenta are γG proteins and these most often appear as a consequence of immunization with incompatible erythrocytes.

Maternal plasma γA and γD immunoglobulins do not cross the placenta although the molecular weights of these proteins are similar for the most part, to that of γG nor does the conceptus synthesize these proteins. Consequently the infant is born lacking these antibodies as well, which in some ways can be a blessing most of the reagins responsible for immediate hypersensitivity reactions such as the wheal and flare response hayfever allergic asthma and the like are γA proteins [40 41] as are some isohemagglutinins. Blocking antibodies are usually γG proteins, and, of course do cross the placenta The synthesis of γA becomes evident beginning about two weeks after birth, but the plasma levels may not reach those of adults or approximately 90 mg % (Table 1) until the child reaches two to four years of age The maturation of γD synthesis remains to be clarified, and even less is known of the synthesis of the low molecular weight γ globulins.

The maturation of immunoglobulin synthesis is the product of the differentiation and maturation of those cells responsible for that synthesis. And the heterogeneity of molecular structure of the immunoglobulins is reflected in the biochemical heterogeneity of those cells which synthesize them The cells responsible for γG globulin production are primarily cells of the so-called plasma cell series, although there is evidence to indicate that γG synthesis also occurs in cells morphologically indistinguishable from lymphocytes, and some γG synthesis is apparent in cells found in germinal follicles of the lymphoid tissues [42–45] On the other hand, γM synthesis has been shown to take place in lymphocytoid cells [45 46] similar to those predominant in Waldenström s macroglobulinemia which do not develop into plasma cells and appear to be a separate cell line [46] Similarly γA is formed in cells which do not synthesize γM or γG but these cells are morphologically indistinguishable from the cells producing the latter proteins [47 48] A cell synthesizing one class of immunoglobulins does not synthesize another immunoglobulin class and there is evidence to indicate that

a given cell will synthesize molecules of only a single genetic type despite the number of different types that may be synthesized by a single person [15 49]. In fact, it would even appear that a given cell can synthesize only one antibody or molecules of a single specific structure, and at most only two or three different antibodies, indicating that each immunoglobulin synthesizing cell has a limited active DNA RNA code for antibody synthesis [50 51]. The plasma concentration of a given immunoglobulin can be correlated, qualitatively at least, with the numbers of specific immunoglobulin producing cells in the tissues.

Since γG synthesis does not materially increase in the human infant until approximately one to three months of age and since the γM synthesizing mechanisms are capable of stimulation at the time of birth, it is evident that the normal infant given such antigens as pertussis vaccine or diphtheria and tetanus toxoids at birth can synthesize specific antibodies and that these antibodies would primarily be γM proteins. Dancis and his colleagues have shown that the antibody response in the newborn stimulated antigenically at birth is somewhat delayed compared to a similar injection in a child of several months, or seven to ten days after injection as compared to three to four days, and that it is quantitatively smaller. Thus, although small, the amount of antibodies produced by antigenic stimulation at birth confers a degree of protection otherwise absent and can provide an immunologic sensitization or memory for succeeding injections of the same antigen; a second injection in the same infant at one month of age, for example can result in a greater and more rapid synthesis of specific antibodies than a first injection in an infant of the same age. The presence of significant amounts of specific maternal γG antibodies in the infant at birth, however may directly or indirectly influence the effectiveness of immunizations begun at birth. Infants possessing maternal diphtheria antitoxin at birth can, nevertheless, produce diphtheria antitoxin in response to diphtheria toxoid at least half as well as infants born without such antibodies as has been shown by Dancis, and with time the levels of antitoxin in the two groups of infants will be similar. This may be attributed to the observation that specific γM antibody synthesis may be inhibited by the presence of γG antibodies of similar specificity: under these circumstances, the synthesis of specific plasma antibodies will be delayed and will rise more slowly than in newborn infants without such maternal antibodies until the γG system matures further. The presence of relatively high concentrations of specific maternal γG antibodies can prevent effective vaccination *with some live viruses*, such as the modified polio viruses, by impeding even subclinical infection and thus prevent adequate antigenic stimulation.

Careful study of the sequence of antibody synthesis has revealed that, in children or adults, γM antibodies are the first to be detected in response to a specific antigenic stimulus followed by γG antibodies [52]. It will be noted from Table 1 that the molar rate of γG synthesis is approximately 20 to 30 times that of γM, however the effectiveness of γM in those detection tests commonly used, such as hemagglutination, is several hundred times that of γG. As a consequence of these

data, the apparent temporal sequence of γM and γG antibodies can be explained on the basis of the kinetics of separate molecular species rather than any transformation of synthesis from one type to the other the γM antibodies appear to be synthesized first, because of their greater effectiveness in the detection system In young infants, the apparent temporal γM to γG sequence is greatly exaggerated, also a matter of kinetics since the maturation of γM synthesis occurs earlier than γG synthesis. some antigens such as typhoid H antigen, stimulate the synthesis of primarily γG antibodies in older children but in the young infant, anti typhoid H antibodies are predominantly γM proteins on the basis of hemagglutination or hemolysis tests. Some antigens it should be noted do not stimulate much specific γG synthesis. the principal antibodies formed to typhoid O antigen, for example from young infants to adults, are γM proteins.

Deficient immunoglobulin synthesis If the synthesis of each of the three major immunoglobulins γG γA and γM is considered to be an independent variable the simple presence or absence of each of these proteins would result in eight different phenotypes (Table 2) Seven of these possibilities have been described [53–59] and of the six known anomalous states at least four have been shown to be hereditable and one of the latter agammaglobulinemia, is attributable to more than one genotype [60–63] Those conditions characterized by a deficiency or absence of γG synthesis alone or in combination with other immunoglobulin deficiencies are associated with severe recurrent bacterial infections, usually pulmonary deficient synthesis of both γA and γM (type 2 dysgammaglobulinemia) is also associated with recurring infection. However deficiencies of either γA or γM alone without other associated immunoglobulin deficiencies are frequently but not invariably found to be accompanied by such infections and such synthesis deficiencies may occur in otherwise immunologically normal individuals [36 59 63]

One disorder of immunoglobulin synthesis, agammaglobulinemia occurs in at least three different forms: (1) a congenital form the onset of infections beginning in infancy or early childhood, (2) a form frequently referred to as acquired or adult agammaglobulinemia, and (3) a transient condition which occurs in infants beginning at two to three months of age The congenital form can be differentiated into two conditions. (1) a sex linked recessive characteristic occurring in males and transmitted by the female, and (2) a condition found in female infants. The congenital disorder found in the female may represent the younger portion of the age spectrum which is associated with the so-called acquired or adult form the onset of infections in adult agammaglobulinemia occurs at any age from 7 to 70 years, but it is found in both males and females. Despite a lack of documentation of the hereditary nature of agammaglobulinemia in some male infants with the disorder there is great temptation to classify the condition in male infants nevertheless, as the sex linked recessive form and to relegate female infants with agammaglobulinemia into a separate category if the latter female infants do indeed represent one end of the age spectrum of the adult form of the disease then some of the male infants may have been misclassified In

view of the fact that relatively few siblings of patients with adult agammaglobulinemia appear to develop agammaglobulinemia as compared to siblings of patients with sex linked congenital agammaglobulinemia, the distinction is of some prognostic importance to the remainder of the family. Unfortunately at the present time, it is not possible to distinguish between the male infant with the sex linked disorder and the hypothetical male infant who may have a less penetrable genetic state as in adult agammaglobulinemia.

The consequence of deficient immunoglobulin synthesis as exemplified by the agammaglobulinemic state is a marked susceptibility to recurrent serious infections, *primarily bacterial*. In most instances the lungs are the most frequent area of serious attack, but meningitis and septicemia are also frequently observed. In most instances, the agammaglobulinemic state is not absolute and some γ-globulin synthesis does occur: the overall γG range found in this condition, for example, is from 0 to 100 mg %, and in the congenital form it is usually 10 to [illegible] mg %. Small quantities of neutralizing antibodies against some viruses can be demonstrated [64] and in the case of measles at least, the theoretical amount of specific antibody synthesized would seem to be enough to confer protection [62]. In addition, immunity against some viruses such as vaccinia and varicella appear to be dependent for the most part upon a biochemically intact lymphocyte population and in most agammaglobulinemic individuals the lymphocytes retain their capacity to synthesize cellular antibodies [61, 62, 65, 66]. Consequently viruses do not seem to play any more havoc in the agammaglobulinemic individual without lymphopenia than in the normal person, the agammaglobulinemic person who recovers from a viral infection usually demonstrates a normal resistance against reinfection with the same virus unless the disorder is accompanied by lymphocytic hypoplasia. As would be expected, all of the lymphoid tissues in the agammaglobulinemic without lymphocytic hypoplasia reveal a marked deficiency or complete absence of plasma cells and the virtual or complete absence of cells capable of synthesizing any of the other immunoglobulins as well, in addition, the lymph nodes, spleen and gastrointestinal tract have virtually no germinal follicles. Although the thymus is *dysplastic, it is quite* what would be expected in the child afflicted with repeated life-threatening infections, and contains both lymphocytes and Hassall's bodies [67]. Interestingly, the lymphoid tissue represented by the tonsils and adenoids is absent, nevertheless, the lymphoid tissues with the exception of the tonsils and adenoids, have a relatively normal complement of small lymphocytes, and the peripheral or circulating lymphocytes are normal in both number and apparent specific function.

There are conditions which are distinguished by *deficiencies in the synthesis of* a specific antibody without any obvious decrease in overall immunoglobulin synthesis. In children with leukemia or cystic fibrosis, for example, and occasionally in a normal child as well, measles virus may cause fatal giant cell pneumonia associated with an absence of neutralizing or complement-fixing antibodies against the virus [68]. Progressive vaccinia has in some instances been associated with an absence

of anti vaccinia antibody synthesis. But it should be cautioned that the absence of specific antibodies in both of the situations just described is not necessarily related to the failure in resistance against the specific virus. In the case of children with leukemia or cystic fibrosis who develop measles giant cell pneumonia pooled γG which contains anti measles antibodies fails to check the measles virus and in progressive vaccinia, the principal deterrent to the infection is not specific humoral antibody but cellular antibodies formed in lymphocytes. Another example of a specific antibody deficiency is the absence of isohemagglutinins in the Wiskott-Aldrich syndrome but the relation between the disease and the deficiency has not been clarified.

Transient hypogammaglobulinemia is attributable to a delay in the onset of γG immunoglobulin synthesis beyond one to three months of age [60] Since γG obtained from the mother is degraded, under these circumstances the γG concentration in the infant will fall below 150 mg% by the time the infant is two to five months of age and the child will be vulnerable to serious bacterial infection. Fortunately the failure in γG synthesis is temporary and by the time the child is 7 to 15 months of age significant γG synthesis becomes apparent It has been postulated that this form of hypogammaglobulinemia is due to an incompatibility of γG Gm types between mother and fetus with synthesis of maternal antibodies against the Gm type of the fetus: although most anti Gm antibodies are γM proteins, on rare occasions they may be γG and could therefore pass the placenta from mother to fetus [30 60] The theory requires that such maternal antibodies would suppress those fetal cells synthesizing the specific Gm molecule. The theory remains to be proven but there is considerable evidence in animals to give it plausibility

The Thymus and the Lymphocyte

The most readily observed manifestation of cellular antibody synthesis is the dermal delayed hypersensitivity reaction, a specific induced sensitivity to an antigen which is demonstrated by the intradermal injection of the antigen and manifested by an area of erythema which appears usually within 12 hours, reaching a maximum within 48 hours after injection and subsides gradually sometimes taking several days or more to disappear This type of reaction is also exemplified, however by the sudden exudative reaction in primary pulmonary tuberculosis that may occur in one to two weeks after infection and by the sudden extension of erythema and induration around the site of vaccinia inoculation at seven to ten days after the vaccination, both are specific reactions against antigens at the tissue site mediated by cellular antibodies As is clearly shown by the work of Waksman and his co-workers, the cell responsible for the synthesis of such cellular antibodies is the small lymphocyte. The delayed type of hypersensitivity to a specific antigen can be transferred to a nonsensitive recipient by means of peripheral cells in the circulation of a sensitive donor or by means of cells from lymphoid tissues of the donor it cannot be transferred by means of plasma in contrast to the immediate or wheal-and flare type of hypersensitivity which is attributable to humoral antibodies. The delayed type of hypersensitivity

to specific antigens can also be transferred to nonsensitive recipients by means of extracts of sensitized lymphocytes [70–72] or by means of a transfer factor [73] isolated from such extracts, the factor having a molecular weight of 700 to 4000 and containing nucleic acids [74]. The transfer factor apparently passively sensitizes the recipient's lymphocytes and, once induced, the hypersensitivity may last from weeks to months depending upon the amount of factor used. Passive transfer with sensitized viable lymphocytes can induce hypersensitivity which may remain for years.

By eight to ten weeks gestation, lymphocytes are present in the blood and tissues of the human embryo. By the time of birth, the lymphoid tissues are well populated, though certain areas, such as the appendix, do not have nearly as many lymphocytes as will be present within the year and the lymph nodes lack both primary and secondary follicles. By three months of age primary follicles may be evident as well as an occasional germinal follicle, and by one year of age the architecture of the lymphoid tissues is similar to that in the adult. There are, however, several populations of lymphocytes, the differentiation of the small lymphocyte appears to be related to normal development of the thymus, but some lymphocytes which morphologically appear as medium or large lymphocytes are not under thymic control. The peripheral lymphocytes come from the lymphoid tissues and at least two groups of lymphocytes can be distinguished: one group which appears to arise primarily from lymph nodes, the spleen and the gastrointestinal tract, and another which comes from the bone marrow restricted areas of the spleen and the appendix. The lifetime of the peripheral lymphocyte, at least in the adult, is at least one year and more likely two years.

The role of the lymphocyte in preventing infection in man is best observed in the condition thymic alymphoplasia, a failure in the development of the thymus as manifested by a primitive thymus which is made up principally of reticulum cells, has no Hassall's bodies and is virtually devoid of lymphocytes [67, 75–78]. Patients with thymic alymphoplasia also have lymphocyte hypoplasia, or a marked paucity of lymphocytes in all lymphoid organs, including the tonsils and adenoids, and most demonstrate alymphocytosis or a lymphopenia below 1500 cells per cu. mm. The development of the thymus, and hence the small lymphocyte, is independent of the development of the immunoglobulin synthesizing cells [79, 80], so that patients with thymic alymphoplasia may have normal rates of immunoglobulin synthesis or may show deficiencies in the synthesis of one or more immunoglobulins (Table 2).

The presence of persistent lymphopenia is a suggestive aid in the diagnosis of thymic alymphoplasia, but it must be emphasized that some patients have normal blood lymphocyte counts. A lymph node biopsy or a rectal biopsy carefully studied is probably the most reliable single diagnostic aid. The peripheral lymphocytes do not repopulate the lymphoid organs, including the thymus.

Thymic alymphoplasia thus far has invariably terminated fatally, usually within the first two years of life [67, 75]. Children with this disorder, with or without associated immunoglobulin deficiencies, are

afflicted with almost intractable continuous infection In almost all instances pulmonary infections dominate the clinical picture but intestinal infection, and systemic or oral moniliasis play a significant part in many At some point during the course of the disorder an exanthem is seen in some These children cannot actively develop delayed hypersensitivity since they lack small lymphocytes, but they can be passively sensitized using viable lymphocytes from a sensitive donor [66] Interestingly they do not reject skin grafts. Thymic alymphoplasia is transmitted either as a sex linked autosomal recessive characteristic appearing in males or as an autosomal recessive occurring in both males and females. The course of this disorder is not ameliorated with pooled γG therapy

Thymic alymphoplasia has been also found in a rare condition known as reticular dysgenesis a state characterized by alymphocytosis, agranulocytosis, lymphocytic hypoplasia and an absence of granulocyte precursors in the bone marrow These children have died of overwhelming infection soon after birth [77 78]

Any attempt to relate the differentiation of the lymphoid and immunoglobulin systems in a coherent fashion certainly requires far more evidence than is now available But on the basis of studies of abnormal lymphocyte and immunoglobulin synthesis, a vague picture appears to be emerging To theorize then, on the basis of such evidence as has been referred to in this discussion, the pattern of cellular differentiation in Fig 3 is offered It will be noted that the failure of differentiation of primitive cell *A* would result in thymic alymphoplasia and agranulocytosis as

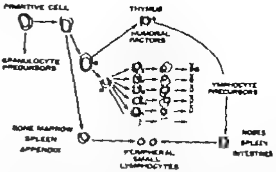

Fig 3 A proposed scheme of the differentiation of immunologically competent cells responsible for synthesis of the specific immune factors. On the basis of the immunological deficiency disorders discussed in the text, the differentiation sequence from primitive cell *A* to cell *C* presumably takes place before 8 to 10 weeks gestation. The differentiation of cell *D* to cells *E* to *J* or the differentiation of cells *E* to *J* to immunologically competent cells would appear to take place at different later periods of gestation, cell *G* having differentiated by 12 weeks gestation and cell *E* by 24 to 28 weeks gestation.

noted in reticular dysgenesis, whether or not agammaglobulinemia is also a part of the picture of reticular dysgenesis as predicted by this scheme is not known. Failure of cell *B* to develop would presumably result in thymic alymphoplasia and agammaglobulinemia with alymphocytosis whereas failure at the level of cell *B′* would result in thymic alymphoplasia and agammaglobulinemia without alymphocytosis. Failure of cell *C* to differentiate would result in thymic alymphoplasia with relatively normal immunoglobulin synthesis rates, whereas failure in cell *D* would result in agammaglobulinemia without thymic alymphoplasia It was pointed out at the beginning of this discussion that the different plasma immunoglobulins are synthesized in different cells and that each cell synthesizes only a single or at most a limited number of different immunoglobulin molecular structures For simplicity the differentiation of only the individual

immunoglobulin classes based on the synthesis of different heavy chains is depicted in Fig 3 but it is recognized that the cells of each class differentiate further to the point where only *one to three* different antibodies are synthesized per cell. Failure of one or more but less than all, of the cells synthesizing the individual γ-globulin classes would result in dysgammaglobulinemia.

An attempt has been made here to correlate some of the generally accepted present concepts *of the structure* function and *metabolism* of antibodies in relation to the pattern of immunity against infection manifested at various stages of human development But if any truth is absolute it is that the future will undoubtedly prove the present *to be at least partly if not* entirely wrong

Main Features of the Congenital Nephrotic Syndrome

by NIILO HALLMAN HEIJO NORIO and KAUKO KOUVALAINEN

The congenital nephrotic syndrome or congenital nephrosis (CN) is a rare disease showing signs of lipoid nephrosis already at birth or at least in the course of the first few weeks of life [2, 4, 5, 6 7 22]. In Finland CN is much more common than anywhere else. That has been a natural impetus for comprehensive studies on CN in this country [6 7 8, 9 10 12, 13 14, 16, 17 19 21].

Though CN greatly resembles the acquired form of the idiopathic lipoid nephrosis of childhood, it has, however several pathognomonic or characteristic symptoms and signs. CN is a familial disease. In most cases the intrauterine onset of the disease is clearly evident

1 Nearly unexceptionally the placenta is very large i.e more than 25 per cent of the birth weight [12];

2. The birth weight is low which, at least partly derives from prematurity [6, 7 13];

3. Proteinuria and the nephroti serum protein pattern are seen immediately after birth in a great majority of cases [6 7 13];

4. Wide cranial sutures at birth indicate that the ossification process is delayed already *in utero* [8];

5. Polycythemia and especially the advanced erythroblastosis occasionally seen in neonatal CN patients probably derive from impaired function of the large edematous placenta [8].

The patients may show edema at birth or it develops in the course of the first few days, or occasionally weeks of life. Ascites and meteorismus often cause a marked bulging of the abdomen and the appearance of hernias in the more advanced cases. The patients usually lie in a position similar to opisthotonus. This is very probably due to the discomfort caused by the bulging abdomen. The ankles are very often flexed in the calcaneo-valgus position since birth. The cartilages are soft, which probably causes the peculiar face in CN (Fig 1)

CN is an unexceptionally fatal disease. Medication with corticosteroids seems to be *of no value*. The *physical development* is extremely poor Most of the patients succumb to infections at the age of *few* months. The longest life-span of a CN patient in Finland has been three years and 10 months. The biochemical findings of CN are principally similar to those of acquired lipoid nephrosis. One chemical characteristic of CN is the elevation of the gamma-M immunoglobulin. The renal function remains good in most respects [8, 12]

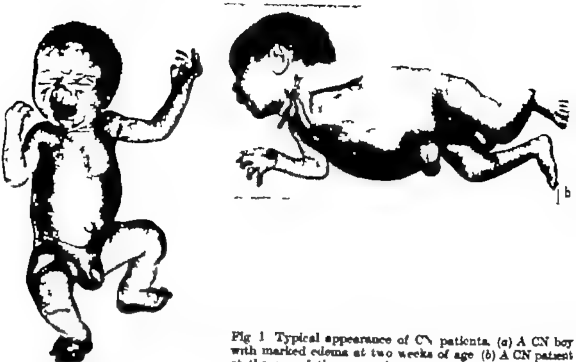
Fig. 2. A map showing the distribution of the known CN families by countries up to 1966. A black dot indicates one CN family with one or more sick children.

Nearly one third of the marriages of CN parents are consanguineous, even if rather remote. A great number of close or distant relationships between several CN parents were disclosed. Thus, 10 CN parents could be shown to be descendants of one and the same ancestor pair living in the 18th century. The ancestry of CN patients was found to be concentrated in certain areas in the country. The recessive transmission associated with some peculiar genetic conditions of the population in Finland, dealt with in the study mentioned, seems to explain the abundant occurrence of CN in this country.

Though it is now known that CN is an inherited disease, the pathogenesis is still obscure. Whether the basic lesion in CN is a renal malformation [3, 17] or an inborn error in protein synthesis of the basal membrane of the glomeruli and perhaps in the synthesis of other proteins [16], or whether the frequent immunological features associated with CN play a causal role [12, 14, 15], remains to be clarified.

Summary

Until now 85 patients with an evident congenital nephrotic syndrome have been recorded in Finland. The main features, incidence and etiology of CN are dealt with in this report.



a b

Fig. 1. Typical appearance of CN patients. (a) A CN boy with marked edema at two weeks of age. (b) A CN patient at the age of three months. Note the bulging abdomen, hernias and the opisthotonic position.

Patho-anatomically the most prominent changes are seen in the kidneys. They are large and pale and show microcystic dilatations of the proximal tubuli, often a swan-like neck, and regularly glomerular changes. These consist of proliferation of glomerular cells, crescent formations, the presence of polymorphonuclear leukocytes, and thickening of the capillary walls. By electron microscopy the most constant findings are fusion of the foot processes of the epithelial cells and nodular thickening of the endothelial side of the capillary basement membrane [3, 5, 7, 8, 9, 10, 17, 21, 22]. Round cell infiltrations are often seen in the kidneys and the heart. The liver and the spleen often show signs of erythropoesis. Interstitial pneumonia is a common finding at autopsy [8, 15].

The occurrence of evident CN families known to us in the world is presented in Fig. 2. Though there are 46 reported CN families from 17 other countries [1, 2, 3, 4, 5, 11, 15, 18, 20, 22, a complete list is given in reference 16], the accumulation of CN in Finland is striking. Finland has a population of about four and half million. Until now 85 Finnish CN cases from 66 families have been detected. The mean annual number of verified CN children born in Finland in the last ten years has been seven, which roughly gives the rate of one CN child per 10 000 deliveries.

Recently a genetic study [16] on the comprehensive Finnish family series has given definite evidence in favour of an autosomal recessive transmission of CN. Thus, the corrected proportion of affected siblings is very close to the theoretical value of 0.25 (0.250 according to complete truncate ascertainment in families whose parents were married in 1950 or later).

Some Reflections on Pediatric Teaching

by L. EMMETT HOLT JR.

It is a pleasure to contribute to a volume in commemoration of Professor Constantin Choremis—an outstanding pediatrician from every point of view who combined to a high degree the attributes of the clinician, the teacher and the investigator

In the course of the past 50 years in which I have been in medicine I have witnessed or participated in a number of techniques and experiments in medical teaching, and it occurs to me that it might be of interest to discuss them even though in the last analysis it is difficult to draw firm conclusions regarding their merits, for controlled studies of teaching procedures are not available.

When I first studied medicine during the time of World War I, the pattern of medical teaching in the United States was heavily influenced by European and particularly by German medicine—it might be called the Geheimrat pattern. The professor who did virtually all of the teaching of a clinical subject was a man on a pedestal Somewhat of a Czar his word was never challenged by any staff member He was, as rule the sole examiner of students. He was the repository of all knowledge in his specialty the possessor of an extensive private library to which few if any one else had access. He was an expert clinician and much sought after as a consultant. We owe a great debt to this group of people who were indeed the founders of pediatrics.

A different pattern developed, mostly after World War I, and has since become quite widespread. It was the era in which research became glamorous. Research in pathology there had been, but research on living subjects—clinical research, with the tools of biochemistry and immunology that was something new In time it affected the prestige of the pure clinician, skillfull though he might be. As knowledge advanced it was no longer possible—even in a branch of medicine such as pediatrics —for one man to encompass it all. Subspecialization in pediatrics began to grow in the late 20s and has been steadily on the increase since We now have and must have pediatric cardiologists, pediatric endocrinologists, pediatric hematologists, subspecialists in neonatal disease in neurology in pulmonary physiology in many other branches of disease. It is impossible for one man to keep up with the continuous

Some Reflections on Pediatric Teaching

by L. EMMETT HOLT JR.

It is a pleasure to contribute to a volume in commemoration of Professor Constantin Choremis—an outstanding pediatrician from every point of view who combined to a high degree the attributes of the clinician, the teacher and the investigator

In the course of the past 50 years in which I have been in medicine I have witnessed or participated in a number of techniques and experiments in medical teaching, and it occurs to me that it might be of interest to discuss them even though in the last analysis it is difficult to draw firm conclusions regarding their merits, for controlled studies of teaching procedures are not available.

When I first studied medicine during the time of World War I the pattern of medical teaching in the United States was heavily influenced by European and particularly by German medicine—it might be called the Geheimrat pattern. The professor who did virtually all of the teaching of a clinical subject was a man on a pedestal Somewhat of a Czar his word was never challenged by any staff member He was, as a rule, the sole examiner of students. He was the repository of all knowledge in his specialty the possessor of an extensive private library to which few if any one else had access. He was an expert clinician and much sought after as a consultant. We owe a great debt to this group of people who were indeed the founders of pediatrics.

A different pattern developed, mostly after World War I, and has since become quite widespread. It was the era in which research became glamorous. Research in pathology there had been, but research on living subjects—clinical research, with the tools of biochemistry and immunology that was something new In time it affected the prestige of the pure clinician, skillfull though he might be. As knowledge advanced it was no longer possible—even in a branch of medicine such as pediatrics —for one man to encompass it all. Subspecialization in pediatrics began to grow in the late 20s and has been steadily on the increase since. We now have and must have pediatric cardiologists, pediatric endocrinologists, pediatric hematologists, subspecialists in neonatal disease, in neurology in pulmonary physiology in many other branches of disease It is impossible for one man to keep up with the continuous

spread of subspecialization. It is impossible to keep up with the enormous expansion of the literature and it has become increasingly difficult for one man to teach with the newer diagnostic techniques. The team approach has come. Departments of pediatrics have had to expand, have had to depend more and more on individuals with specialized knowledge. Libraries, too are now seldom private and access to new knowledge has become the right of the youngest physicians. It has brought a loss of prestige to the all-encompassing leaders. As they pass on, they are not being replaced by their likes; the prized individual is the man who can create knowledge rather than just dispense it. Leadership and personality there must be and organization. The professor of today needs to be a general who can organize an effective army—one who can effectively coordinate individual skills.

One characteristic thing about Americans is that they are always trying something new. This is true in teaching of pediatrics as well as of medicine in general. As pediatrics emerged as a respectable specialty, there was an urge to increase its status by acquiring more and more teaching hours for it in the curriculum. Questionnaires were circulated to the various medical schools. It fell to my lot to estimate the number of hours devoted to pediatrics at Johns Hopkins where I was at that time. Johns Hopkins was without much doubt the leading pediatric center at that time. Many distinguished pediatricians had been trained by Dr Howland including more than a dozen department heads, but it appeared that only 96 hours had been devoted to pediatrics as compared to a national average of over 200 hours. It was quality than quantity which counted.

A number of different techniq interest students in pediatrics have employed in our country. One w *catch the student early* even in his year when he is bored by anatomy perhaps depressed by the complexit biochemistry and show him some pediatric patients and that pediatrics a real live subject. I have participat several of these attempts. These prog were always popular with students, sooner or later all were abandoned. T took up too much faculty time an was eventually felt that unless a stu had enough imagination to know w was coming and to see the necessity putting his nose to the grindstone w his anatomy and biochemistry, he pr ably wasn't worth much.

Interdisciplinary teaching is someth that nearly every medical school has ex rimented with. The clinical-pathologi conference is, however, almost the o manifestation of this technique that h survived. The greatest interdisciplina teaching effort—one that is still going —is that employed in Cleveland at We tern Reserve Medical School. Teaching by organ or by system rather than by th familiar medical disciplines. A studen takes up the liver, dissects it, looks at i under the microscope, studies its func tions, poisons it and sees it in various dis ease states. Then he goes on to th spleen, the alimentary tract, the circula tory system, the lung, the nervous system, etc. He sits at one desk for his first two years. One drawer of this desk is his anatomy laboratory—an air conditioned drawer containing an infant's cadaver

Another drawer contains a microscope. A part of his desk rolls back to reveal a chemical laboratory—and so it goes. The plan seems to work well for the first two years and attempts are being made to extend it into the later years, though more difficulties have been encountered there. It appears that eventually the student at Western Reserve learns the same things as are taught in other medical schools, but in a different order. What has been gained is still an open question, but two positive items stand out: (1) Western Reserve has received a lot of money to carry out this experiment and (2) the experiment engendered considerable enthusiasm among teachers to make it work. It is hard to balance this up against possible deficits—time lost in reorganization, time taken from other functions of a medical school. The effort to revamp our conventional disciplines could, unless generally adopted, lead to administrative difficulties—to departments of hepatology or splenology rather than to departments of medicine, surgery and pediatrics, which would make it difficult for an individual to migrate from one school to another.

A general trend in American pediatric education has been the gradual replacement of the formal lecture given to an entire class by informal teaching to small groups. In some institutions formal lectures have been dispensed with altogether. This trend is, I think, sound and makes for better teaching. The difficulty is its cost in time. One year while I was at Johns Hopkins we decided to go all the way and abandon formal whole class exercises altogether. The 60 odd students were divided into 8 groups of 7 or 8 each and an instructor stayed with his group for the entire year giving them informal conferences once a week. There were real advantages in this plan. It made for a very intimate relationship between student and instructor. The difficulties were two—(1) the number of instructor hours devoted to teaching encroached to some extent upon the research activities of the staff, and (2) not all the instructors were equally talented as teachers; the groups assigned to younger instructors felt somewhat shortchanged as compared to the group fortunate enough to have the professor. It was an enjoyable teaching year but we abandoned it for these two reasons and went back to a hybrid course—part lectures and part informal conferences.

The content of a pediatric course is a much discussed subject. The enthusiastic teacher is bedeviled by the prospect that a student may graduate from medical school without knowing anything about this or that and pretty soon he wants the whole textbook covered. The student is faced with a great deal of memorizing much of which will be promptly forgotten and never used. It should be realized that one can't make pediatricians out of all medical students any more than one can make surgeons out of them. One can only expose them to pediatrics—its special problems and how they are approached. Only a *minimum* of factual knowledge is needed. How to think about a problem? How to approach it? What to do to find out more about it? These are the things that should be emphasized for students.

I have been to a number of conferences concerned with pedagogy—with techniques for imparting information to students. Of course the newer audiovisual techniques have been

are valuable but, by and large one must depend on traditional methods. There are good teachers and poor teachers. There is an inborn something in the good teacher that enables him to see into the student s mind. Someone who has it will not talk over the student s head nor will he bore the student There are however a few pedagogical tricks that can be learned My friend the late Paul Lamson, a professor of pharmacology used to watch the students very closely when he was lecturing and he learned how uniform and predictable their reactions were. If he wanted to catch the attention of the class all he had to do was to say now there are just three things about this that I want you to remember The students would all sit up straight, out would come the pencils and the note books. But if he said now I am going to take a few minutes to review for you the physiology of the kidney the students would lean back and relax. A happy medium alternating between these two techniques seemed to work best Continuous stimulation could not be maintained and there had to be periods of relaxation.

In clinical teaching the instructor who can make diagnosis a game has a great asset. By giving out limited information and withholding some he can make the student consider a wider spectrum of possibilities. A bandage can be put on to conceal a tuberculin reaction or the site of a lumbar puncture to make the discussion more interesting before the final and perhaps dramatic denouement There is an advantage in teaching by the Socratic method—asking the student questions that will make him think. I can recall one of my teachers—this time a neurologist—who had no objections to faking a lectu demonstration to illustrate a point If h had no patient on whom he could de monstrate a tabetic gait or the hyperactiv reflexes of general paresis he would trai one to perform. The important thing i his opinion was to leave the typical pi ture in the student s mind.

There are bad pedagogical technique too The instructor who assigns fixed reac ing from a textbook and conducts a qui with the book on his lap fails to inspire hi class. He is bored and so are they

When I was about to leave Baltimor some 20 years ago to take over a pediatr department of my own in New York went first to my chief Dr Park, wit whom all of us had a close filial relation ship, and asked him what he thought should do about teaching His reply sur prised me and may surprise some others He said. 'You don t have to do anythin about it I have come to the conclusio that it takes care of itself Your job is t create knowledge not to pass along dog mas that are traditional and that may b wrong If you produce new informatio you will find that there is always someon in the department—some born teacher— who will tell the students about it. New knowledge is thrilling It makes a dyna mic rather than a static department It puts a premium on the open mind.

A similar thought in slightly different form was expressed by the late Alan Gregg head of the medical division of the Rocke feller Foundation and one of the greatest of our medical philosophers. 'The real purpose of a medical school he said is the education of the faculty I used to hang that quotation on my wall Research means better medical care and better

teaching. The fruits of new work are passed on to the patient. The man who contributes them becomes a better clinician in this area, his teaching becomes the teaching of an expert. This, in a nutshell, is my own philosophy It is the philosophy I have tried to live by in my years at New York University

Restrictive Practices in Paediatrics

by R S ILLINGWORTH

To some extent all children need restriction in their activities. They have to be protected from danger until they are old and mature enough to become independent of supervision All children need to learn discipline they have to learn to conform to custom, to respect the property of others, to behave in a way acceptable to others. All children need to learn to accept a No Some children have to suffer restrictions in their diet either because of a metabolic disease or because of threatening obesity Throughout their childhood and in early adolescence restrictions are necessary decreasing as maturity is reached. This article however is concerned with some undesirable restrictions.

Infant Feeding

After prolonged disagreements about the desirability or otherwise of feeding premature babies early in the first 24 hours, or of delaying feeds for 48 to 72 hours many are now realising that there are distinct advantages in early feeding and disadvantages in starvation. Ylppo of Finland [32] has for many years advocated early feeding He argued that rats tolerate early starvation badly and die within 24 hours. Infants rapidly become acidotic if starved. Several workers have found that delayed feeding of premature babies is associated with a higher serum bilirubin. Hubbell et al [12] studied 48 infants of diabetic mothers, feeding half in the first 24 hours and half after 48 hours. Those fed early had a lower indirect bilirubin than those fed late Smallpeice & Davies [20] working at Oxford, provided further evidence for the desirability of early feeding of premature babies. It now seems clear that early feeding reduces the risk of hypoglycaemia reduces the tendency to acidosis, and keeps the serum bilirubin lower than delayed feeding—all important advantages.

It has long been our practice to feed premature babies about 12 hours after birth. We never found it easy to believe that a delay of 48 to 72 hours would make the baby so much more mature that regurgitation was less likely—and that is one of the main arguments advanced by the proponents of late feeding

We have always advocated self demand feeding of babies in Sheffield Yet there are still some who claim that babies should be fed on a rigid schedule and denied a feed in the night if they awaken and cry for it In the Jessop Maternity Hospital, Sheffield, where the babies are in a crib

at the mother's side, all babies are fed on the self demand method. It is far easier for the nursing staff to supervise feeds where necessary and it greatly reduces the amount of crying.

It is irrational to instruct mothers to feed the baby for an exact time on each breast (usually ten minutes). This ignores the fact that babies differ in the rapidity with which they suck, that nipples vary and that breasts vary with regard to the rapidity of the flow of milk.

There are still many doctors who ascribe vomiting, crying or diarrhoea to overfeeding and then restrict the amount of feeds. I am firmly convinced that overfeeding in a young baby is a myth. Babies know when to stop, just as lambs, calves and other animals do. I have never seen lambs or calves vomiting as a result of overfeeding. It would be strange if they knew when to stop, while human babies did not. I strongly believe that young babies should be given as much as they want.

There is no justification for laying down the exact age at which a child should be weaned on to thickened feeds. If it is thought desirable thickened feeds can be given to three or four week old baby.

Special diets have to be given to children with such metabolic defects as phenylketonuria, leucinosis, galactosaemia, fructose or sucrose intolerance, hypercalcaemia, and coeliac disease and dietetic restrictions are necessary for all these conditions, and for certain similar disturbances. Dietetic restriction is unjustified, however for many conditions for which restrictions are still applied by many. Examples are infective hepatitis and nephritis.

Crews & Faloon [4] showed the fallacy of giving a low fat diet in liver disease and reviewed the literature. It has always been our practice to give children with infective hepatitis a normal diet with unrestricted fat unless they wished to have a low fat diet, which is unusual. Nefzger & Chalmers [21] have shown that a high protein diet shortens the duration of illness.

I see no reason to restrict the protein in diet for acute nephritis, unless there is severe oliguria, which is rare, in children. We conducted a controlled experiment with low protein and high protein diets, [13] and found no difference in the rate of healing. Neither do we see the need for the restriction of fluid or salt in acute nephritis except in the rare cases of severe oliguria. It is unpleasant for the child and achieves nothing. It is quite irrational.

In the case of gastroenteritis and diarrhoea, opinions differ about the need for dietary restriction. Holt [10] has long advocated normal milk intake in infantile gastroenteritis. Mitchell *et al.* [20] studied 396 cases of diarrhoea, comparing the effect of early feeding with the usual starvation. Those fed with milk did as well as the starved ones. O Keefe [22] conducted a similar study and found that babies given milk had more bulky stools, but absorbed more and did as well or better than those babies which were starved. In the case of ulcerative colitis, however Wright & Truelove [31] have shown by controlled experiments that a milk free diet is of value in some patients.

In treating an older child with diarrhoea (e.g. due to dysentery) I would not restrict the diet. I find it difficult to believe that when the intestinal contents are liquid or semiliquid, as they are the avoidance of ordinary solid food can possibly make any

difference to the course of an attack of diarrhoea

With regard to diabetes, there is a legitimate difference of opinion about dietary restriction. One must do anything possible to reduce the high incidence of arterial changes after a few years and Wilson *et al* [29] showed how poor control of childhood diabetes is followed by a higher incidence of arteriosclerosis. Payne & Forsyth [23] however followed 100 diabetic children given a free diet and found that the incidence of arteriosclerosis was as low as or lower than that described by advocates of rigid dietary restriction.

There is no justification for giving a fat free diet for the periodic syndrome (migraine) or for urticaria The latter is far more likely to be due to sensitivity to insect bites than to food allergy which is a rare cause of urticaria

Fig. 1 Swaddled baby in a Leningrad Hospital

Physical Restriction

Swaddling of babies is still practised in some quarters A few years ago I visited Russia and was interested to see all babies in the hospitals and coming up to the hospitals tightly swaddled. In an excellent review of the subject Lipton Steinschneider & Richmond [18] discussed the origin of swaddling and the probable reasons for it. These included the prevention of masturbation, pacification, and an attempt to keep the legs straight. They found in experiments that swaddling does in fact reduce the amount of crying in babies. There is no evidence that swaddling does harm, though one feels some revulsion against the practice

In the past restrictive methods were used for the treatment of masturbation and thumbsucking Levine & Bell [17] quote Holt's *Diseases of Infancy and Childhood* in the years 1906 to 1925 as saying In young children if masturbation is manual the hands should be tied to the side of the crib If masturbation is practised by thigh friction, the legs should be tied likewise to the corners of the crib. No one would advocate such methods now Neither is there any need to stop thumbsucking—at least until the age of six It has been shown that provided the practice stops before 6 no deformity of the teeth will result After that some 14 per cent only will show tooth deformity [8]

There are mothers who deliberately keep their infants (e g at the age of six months or so) off their feet because they think that by so doing they will prevent them

Fig. 2

developing rickets, knock knee or bow legs. I assure mothers that there is no truth in this, and that legs are made to stand and walk on.

Restriction of an older child's activity is said to be one of the causes of overactivity. Wherever possible they should be allowed to run about without restriction. It should be compulsory, as in Copenhagen, to supply adequate playing space when any block of flats is built.

Restriction of activity in children with congenital heart disease or children who have had rheumatic fever with or without carditis, is unjustified. They should be allowed to indulge in as much activity as they feel able to do. The possible exception is congenital aortic stenosis; competitive games should not be allowed.

It is difficult to advise about restrictions in the case of epilepsy. Provided that fits are under control, I feel that no restrictions should be imposed. They should, for instance, be allowed to swim under supervision.

Children with haemophilia or Christmas disease need fewer restrictions if they can be suitably protected by padding (e.g. over the knees) (Fig. 2).

Many children are kept indoors unnecessarily after an infection. I have known children kept indoors when it is several degrees warmer out of doors. This seems to me to be irrational.

Keeping Children in Bed

"The bed is often a sign of our therapeutic inadequacy rather than a therapeutic measure deserving of praise. The bed is *the* nonspecific treatment of our time, *the* great placebo." So wrote Browse [3] in his book *The Physiology and Pathology of Bed Rest*. It seems to be a totally irrational tradition in hospitals to put a child to bed as soon as he is admitted, whatever the disease from which he is suffering. When, on a ward round, I exclaimed about a girl, admitted that morning for investigation of albuminuria, having been put to bed, the ward sister said "No one told me that she should be up and about." I replied "surely the child should be up and about if well enough unless someone instructs you to confine him to bed." Not only in hospital, but in

difference to the course of an attack of diarrhoea.

With regard to diabetes, there is a legitimate difference of opinion about dietary restriction. One must do anything possible to reduce the high incidence of arterial changes after a few years, and Wilson *et al.* [20] showed how poor control of childhood diabetes is followed by a higher incidence of arteriosclerosis. Payne & Forsyth [23] however followed 100 diabetic children given a free diet and found that the incidence of arteriosclerosis was as low as or lower than that described by advocates of rigid dietary restriction.

There is no justification for giving a fat free diet for the periodic syndrome (migraine) or for urticaria. The latter is far more likely to be due to sensitivity to insect bites than to food allergy, which is a rare cause of urticaria.

Fig. 1. Swaddled baby in a Leningrad Hospital.

Physical Restriction

Swaddling of babies is still practised in some quarters. A few years ago I visited Russia and was interested to see all babies in the hospitals and coming up to the hospitals tightly swaddled. In an excellent review of the subject, Lipton Steinschneider & Richmond [18] discussed the origin of swaddling and the probable reasons for it. These included the prevention of masturbation, pacification, and an attempt to keep the legs straight. They found in experiments that swaddling does in fact reduce the amount of crying in babies. There is no evidence that swaddling does harm, though one feels some revulsion against the practice.

In the past restrictive methods were used for the treatment of masturbation and thumbsucking. Levine & Bell [17] quote Holt's *Diseases of Infancy and Childhood* in the years 1906 to 1925 as saying: 'In young children if masturbation is manual the hands should be tied to the side of the crib. If masturbation is practised by thigh friction, the legs should be tied likewise to the corners of the crib.' No one would advocate such methods now. Neither is there any need to stop thumbsucking—at least until the age of six. It has been shown that provided the practice stops before 6, no deformity of the teeth will result. After that some 14 per cent only will show tooth deformity [8].

There are mothers who deliberately keep their infants (e.g. at the age of six months or so) off their feet because they think that by so doing they will prevent them

harm at all. We have always allowed such early ambulation, and recovery has been normal.

Rheumatoid arthritis We are against immobilisation in affected children unless it is essential because of pain. Ansell & Bywaters [2], who have had extensive experience of the treatment of rheumatoid arthritis, wrote that "Every effort should be made to get the patient up walking every day even when health is otherwise reasonable. Only under rare conditions when severe constitutional manifestations, severe pain, severe hip involvement, or flexion deformities of knees and hips are aggravated by ambulation should the child be confined to bed, and then only for short periods. We have seen too much irreversible damage done by bed rest to think that it has an important part to play in the treatment of Still's disease. Muscles and bones waste joints ankylose contractures, calculi and bed sores develop, and above all, time is lost

Rheumatic fever The days of prolonged immobilisation for rheumatic fever are rapidly going At Sheffield we have for many years allowed ambulation as soon as the erythrocyte sedimentation rate has fallen to normal, which, with combined corticosteroid and salicylate treatment, usually means two or three weeks in bed, even if there is carditis [13]. There have been many studies of the effect of early ambulation since then, and all have agreed that prolonged immobilisation is useless and may be harmful. May Wilson [20] for instance who has had extensive experience of the condition, allows children up t or three weeks after instituting corticosteroid treatment. Browne [3] wrote that the one thing that lying down does not do is to rest the heart "The main reason for the use of rest in the treatment of rheumatic fever appears to stem from a fear that it might be unethical to treat it in any other way"

Infective hepatitis. After experience of treating many hundreds of cases of infective hepatitis in the Middle East, I am convinced that immobilisation is an essential part of treatment. Chalmers et al. [5] after a careful study of a mild outbreak in Korea, could find no advantage in bed rest. Others have disagreed. Capps and Barker [4], after studying 8,000 cases in the Middle East, concluded that bed rest was essential, and that activity prolonged the course of the disease and predisposed to relapses.

Poliomyelitis Dorothy Horstmann [11] showed that activity in the 48 hours after the onset of meningism increases the risk of paralysis. Ritchie Russel [25] had previously made the same observation. I feel that as long as fever persists, the child should be in bed. I would certainly keep a child in bed during the stage of meningism, hoping that the degree of paralysis, if any would be reduced.

Muscular dystrophy Dubowitz [7] described the serious harm done by putting children with muscular dystrophy to bed unnecessarily He pointed out that they undergo serious deterioration under these circumstances.

Conclusion Much harm can be done by confining children to bed when they want to be up. It bores them makes them restless and uncomfortable, makes sleep more difficult, and has a bad psychological effect. Children should not be put to bed on account of illnesses without good reason.

the private house it is a common practice to put a child to bed if he develops a cold sore throat headache abdominal discom fort, cough chickenpox or diarrhoea even though the child does not feel that he wants to go to bed. I am totally unable to understand the rationale of such a measure No one has ever explained to me why it should be expected that a child with any a sore throat or chickenpox who would like to sit in a chair reading a book or playing a game, should recover less rapidly than a child reading a book or trying to play a game when sitting in bed

A few specific conditions or groups of conditions will now be considered sepa rately

The common infectious diseases I cannot see the slightest reason why a child with chickenpox rubella, mumps or other in fectious disease if anxious to get up should not do so. I know of no evidence for instance, that bed rest accelerates the recovery from chickenpox or mumps, or reduces the incidence of complications, nor do I understand how it could do In the prodromal stage of measles many children would prefer to be in bed, but as soon as the rash emerges they would prefer to be up and about in the room I see no reason why they should not follow their inclination.

Upper respiratory tract infections If a child has a tonsillitis even with a tem perature of 100 or 101 F I see no reason why he should be confined to bed if he would prefer to sit in a chair reading or playing Gibson [9] studied the value of bed rest in a controlled study of 1 082 cases of respiratory infection, and found that there was no difference at all be- tween the two groups with regard to the duration of the illness or of fever He sug gested that children exert themselves more when in bed than when up and about. He wrote As time went by a distinct impres sion began to form that the children with a high temperature who were up and about seemed to get well just as quickly as the better-controlled children who stayed in bed

Diarrhoea. I know of no evidence that diarrhoea from any cause settles down more quickly when a child is sitting up in bed than it does when he is sitting in a chair

Tuberculosis We have had extensive experience of the treatment of primary tuberculosis and of miliary and meningeal tuberculosis, covering many hundreds of cases of each of these conditions. We have never confined children with primary tu berculosis to bed or restricted their activ ity except in the very rare case in which the child is ill. There is no need to send such a child to a sanatorium unless there are very strong social reasons in connec tion with his home As for miliary and meningeal tuberculosis, we always allowed these children to be up and about the ward as soon as they felt fit for this. The majority would be sitting up at the table in the ward to play games and eat their meals within a fortnight of admission.

Nephritis It used to be the practice to confine children with acute nephritis to bed for prolonged periods. There is no need for this Åkerren & Lindgren in Sweden [1] Joseph & Polani in England [16] and McCrory *et al* in America [19] all carried out controlled studies which showed that early ambulation, as soon as naked eye haematuria had ceased did no

harm at all. We have always allowed such early ambulation, and recovery has been normal.

Rheumatoid arthritis. We are *against* immobilisation in affected children unless it is essential because of pain. Ansell & Bywaters [2], who have had extensive experience of the treatment of rheumatoid arthritis, wrote that "Every effort should be made to get the patient up walking every day even when health is otherwise reasonable. Only under rare conditions when severe constitutional manifestations, severe pain, severe hip involvement, or flexion deformities of knees and hips are aggravated by ambulation should the child be confined to bed, and then only for short periods. We have seen too much irreversible damage done by bed rest to think that it has an important part to play in the treatment of Still's disease. Muscles and bones waste, joints ankylose, contractures, calculi and bed sores develop, and above all, time is lost."

Rheumatic fever. The days of prolonged immobilisation for rheumatic fever are rapidly going. At Sheffield we have for many years *allowed ambulation* as soon as the erythrocyte sedimentation rate has fallen to normal, which with combined corticosteroid and salicylate treatment usually means two or three weeks in bed, even if there is carditis [14]. There have been many studies of the effect of early ambulation since then, and all have agreed that prolonged immobilisation is useless and may be harmful. May Wilson [30] for instance, who has had extensive experience of the condition, allows children up two or three weeks after instituting corticosteroid treatment. Browne [3] wrote that "the one thing that lying down does not do is to rest the heart." "The main reason for the use of rest in the treatment of rheumatic fever appears to stem from a fear that it might be unethical to treat it in any other way."

Infective hepatitis. After experience of treating many hundreds of cases of infective hepatitis in the Middle East, I am convinced that immobilisation is an essential part of treatment. Chalmers *et al.* [6] after a careful study of a mild outbreak in Korea, could find no advantage in bed rest. Others have disagreed. Capps and Barker [4], after studying 3,000 cases in the Middle East, concluded that bed rest was essential, and that activity prolonged the course of the disease and predisposed to relapses.

Poliomyelitis. Dorothy Horstmann [11] showed that activity in the 48 hours after the onset of meningism increases the risk of paralysis. Ritchie Russel [25] had previously made the same observation. I feel that as long as fever persists, the child should be in bed. I would certainly keep a child in bed during the stage of meningism, hoping that the degree of paralysis, if any, would be reduced.

Muscular dystrophy. Dubowitz [7] described the serious harm done by putting children with muscular dystrophy to bed unnecessarily. He pointed out that they undergo serious deterioration under these circumstances.

Conclusion. Much harm can be done by confining children to bed when they want to be up. It bores them, makes them restless and uncomfortable, makes sleep more difficult, and has a bad psychological effect. Children should not be put to bed on account of illnesses without good reason.

Keeping Children Away From School

Very many children are kept away from school totally unnecessarily. At any one time about ten per cent of all school children are away from school in certain large cities in Britain. In only a small proportion of these is such absence from school justified. It seems irrational to me to keep a child away from school and yet to allow him to go to the cinema, travel in a bus and go to the Child Welfare Clinic with his brother. Unnecessary absence from school may bore the child, it worries him because he knows that he is dropping behind in work, work suffers, and it is apt to make a child a hypochondriac. In the case of asthma *it is particularly important*, for worry about school work makes him wheeze more and so he is kept off school still longer. It is a vicious circle which has to be broken.

Children are kept off school because of a cough, or a trivial wheeze, or because of a cold. They are kept off school far too long after the common infectious diseases—because of erroneous ideas of the duration of infectivity. For instance chickenpox is only infectious for 6 days after the appearance of the rash, measles till 5 days after the temperature has settled, mumps until the swelling has subsided, and rubella for 5 days after the appearance of the rash.

Quarantine

It is now widely recognised that quarantine of children exposed to infectious disease is useless, except in the case of smallpox and possibly of poliomyelitis. Smith of Rugby was one of the first to point this out [27, 24]. Others have agreed [28]. Smith reported that in 16 years' experience of 75 outbreaks of infectious disease at Rugby school there was no instance in which the originator knew how he had acquired the infection. In the same period 203 boys who had been exposed to infectious disease were allowed back to school and only one acquired the expected disease at school and there was no secondary case. If strict quarantine had been enforced, 4,224 days would have been lost. If only the susceptible boys had been quarantined, 2,123 days would have been lost. Smith remarked that family doctors go from case to case without spreading the disease.

Quarantine has not prevented the spread of disease. It is hardly to be expected that it would, for children cannot be prevented from mixing with others after school. In any case it is useless if a child has already had the infection, and cannot develop it again. Children cannot carry infectious diseases (except diphtheria, scarlet fever and poliomyelitis). They cannot be infectious in the early part of the incubation period—and it is totally irrational to keep them off school then.

There is no place for quarantine except in the case of smallpox and possible poliomyelitis.

On a par with the folly of quarantine is the refusal to permit relatives to visit their children in infectious disease hospitals. This is quite irrational and inexcusable.

Some other Restrictions in Child Management

There are mothers who will not pick the infant up when he cries in case they will spoil him. This is quite unjustified. Moth

ers who satisfy their babies' basic needs for love, food and comfort, are likely to have much happier babies than those who adopt restrictive practices in these fields.

There are mothers who overprotect their children, never letting them out of their sight, 'smothering' them instead of 'mothering' them and not letting them acquire normal independence. They dress them and feed them long after they should be able to dress and feed themselves. They worry about their child's bowels, and try to make him eat, because they fear that he will not eat enough unless he is forced, cajoled and coaxed to eat. They do not realise that the only cause of a poor appetite in a well child is food forcing on the part of the parents.

Every child has to experience stress. A good example of the psychological effect of complete protection from stress in childhood is the story of John Ruskin. We have described this and other examples of over protection, in a book about the childhood of 450 famous men and women [15].

Overprotection leads to excessive dependence of the child on the mother to insecurity and accident proneness. In the same way excessive strictness and excessive discipline lead to rebellion, insecurity and again to accident proneness. Children must be allowed to develop independence and a sense of responsibility to experiment and to learn.

Conclusion

All children need to learn discipline. Some restrictions are necessary for all children. But there are many undesirable restrictive practices which do harm. These have been summarised.

Keeping Children Away From School

Very many children are kept away from school totally unnecessarily At any one time about ten per cent of all school children are away from school in certain large cities in Britain In only a small proportion of these is such absence from school justified. It seems irrational to me to keep a child away from school and yet to allow him to go to the cinema travel in a bus and go to the Child Welfare Clinic with his brother Unnecessary absence from school may bore the child, it worries him because he knows that he is dropping behind in work work suffers and it is apt to make a child a hypochondriac In the case of asthma it is particularly important for worry about school work makes him wheeze more and so he is kept off school still longer It is a vicious circle which has to be broken.

Children are kept off school because of a cough, or a trivial wheeze or because of a cold. sirable in clinical departments. However the full-time system, with its emphasis upon research has become almost universal in the United States, and has been a major force in promoting the increasing specialization which characterizes American medical practice.

This trend toward specialization has also been fostered by increasingly rapid advances in the medical sciences, which have been responsible for the extraordinary progress in curative medicine and surgery during the past 50 years. This expansion of medical knowledge and of the skills required for its application have lengthened the period of hospital training for future physicians and have forced people into specialization, in order that they may feel competent and comfortable within a finite body of knowledge which they can comprehend. Furthermore the change from empirical to scientific medicine has made the teaching hospital the focus of clinical teaching, rather than the patient's home where the apprentice used to learn medicine at the bedside from his physician master in nineteenth century America. In the teaching hospital, with its laboratories, X-ray department, and well-equipped operating rooms, the student sees modern medicine and surgery being practiced by highly competent specialists He sees acute episodes of serious disease being treated ith spectacular success, but he has little contact with the problems of diagnosis in the home or busy office, with the daily care of patients with the minor illnesses and functional disturbances which make up the bulk of morbidity among the populace, or with the skills required to provide long-term care for the patient confined to his home or handicapped by a serious chronic disease. Nowhere in his career as a medical student or as an intern or resident does he have appreciable contact with teachers concerned with family medical care No wonder that he inevitably gravitates into a specialty or that general practice attracts fewer and fewer graduates from our medical schools.

Meanwhile, socio-economic changes have exerted a tremendous influence upon medical practice. The increasing prosperity of our population, as a result of the diffusion of wealth, education and earning power through an increasingly wide segment of our society has meant better housing, better nutrition, and better health practices in the home, all of which have had a subtle effect in steadily lowering the mortality from infectious diseases quite independently of advances in preventive and curative medicine There has been a marked shift in the pattern of American family life accompanying the transition from what was primarily a rural, small town society to an urban suburban culture brought about by increased agricultural productivity rapid industrialization and the mobility made possible by the automobile This shift has broken up the large multi-generation household of former days and moved the majority of our people into small, single-family suburban houses where parents live crowded in with their two or three children, often far away from other relatives. The grandmothers and maiden aunts who used to play such an important supportive role in bringing up children are no longer available, and the young mother turns to her pediatrician for answers to many questions about childbearing and child development that would never have

sicians is probably longer than for any other profession, no cadre of previously trained reserves is available to meet unexpected demands. Therefore it is extremely difficult to expand health and medical services as rapidly as they are being demanded in today's world

Adjustment of the educational system to meet present and anticipated needs for trained manpower is far simpler in a totalitarian than in an open society such as we enjoy in the United States or in western Europe The system followed in most countries with political freedom has been a "laissez faire" one, in which it has been assumed that financial and other inducements, such as the desire to serve and the desire for prestige would tend to draw manpower into those professions and occupations where the need and hence the demand was greatest. The main difficulty with this system is that needs are now changing so rapidly that the period of at least nine years, which must elapse between an individual's decision to enter the medical profession and his emergence as a trained physician, is far too long for satisfactory adjustment between supply and demand to take place Thus grudgingly our country is being forced to adopt some degree of long range educational planning although it is pluralistic and far less rigid and monolithic than the planning of most totalitarian countries or of those democratic nations where educational policies and the funds for their implementation are practically all under the control of a central Ministry of Education.

It is instructive to examine what has happened to the supply of physicians in our country as a result of the successful efforts by the medical profession to im prove the quality of medical educatio the impact of advances in medical scienc and the socio-economic developments o recent years

In the early twentieth century whe progress in the medical sciences began t make modern scientific medicine possible deficiencies in the scientific education o many of our physicians became increasingly apparent This led the medical profession to examine our system of medical education an examination which culminated in the Flexner report in 1910 This report prepared by a distinguished schol and educator who was not himself a ph sician led to far reaching reforms in mo American medical schools and to the el mination of a large number of medic schools of poor quality The two princip results of the Flexner report were first drastic reduction in the number of place open to those who desired to embark upo a medical career second introduction o the full time system[1] into clinical depart ments The latter step which greatly improved the scientific basis of clinical teaching initiated the great emphasis upon research rather than mere clinical skill, as the criterion for academic advancement which has characterized modern American medical education. This has had far reaching consequences, and it is interesting that one of the major proponents of this system, who accepted the first full time professorship of medicine in the United States in 1914 by 1917 had already come to the conclusion that it was not necessarily de-

[1] The full time system means that the clinical teacher devotes all his time to teaching and research, does not practice for himself and derives his financial support wholly from his academic and hospital salary

where doctors are adequate in numbers, rapid scientific and social changes have rendered their training which is excellent preparation for physicians for the crowded urban areas or the developing countries, unsuitable to enable them to cope in a professional manner with the multitude of minor illnesses, functional disturbances and family stress situations which turn out to be such frequent problems in suburban practice.

We have shown how medical education has failed to produce the number of doctors needed or demanded by our society today and that the available doctors are neither equitably distributed nor properly trained for the demands of modern practice. All of these deficiencies may be explained on the basis that the rate of change—both in medicine and in our society—has outstripped the capacity of our educational system to adapt to it. University medical schools have been so engrossed in the extraordinary successes of the medical sciences in overcoming the life-threatening and crippling diseases which are concentrated in our teaching hospitals that they ha failed to pay adequate attention to the overall health needs of the community or to examine scientifically the ways in which medical knowledge can most effectively be pplied to improve the health of our people. Fortunately this is changing. Medical care is becoming the subject of intensive investigation in a number of medical schools; furthermore the provision of comprehensive care to urban poor families is now being undertaken, with government support, by medical schools and hospitals in our larger cities. With research tools derived from the behavioral sciences—cultural anthropology sociology psychology statistics—it should be possible to study medical practice and to experiment with it at a family level, so as to achieve more *effective* ways of applying our enormously potent biological knowledge to the improvement of health.

In this essay specialization has been mentioned frequently as an inevitable consequence of scientific advances, but as an evil in that it has increasingly deprived our society of the general practitioners which it needs. Since scientific progress is bound to continue, it seems inevitable that specialization in medicine will continue to increase rather than diminish. Who then is going to meet the health needs of families, who is going to provide primary medical care in this day when most doctors, already in short supply are becoming specialists?

Several possibilities suggest themselves to meet the needs of families for comprehensive health and medical care. The first is *group practice*, whereby doctors representing a number of specialities work together in providing medical care in a given community. This method of practice has proven to have many advantages in private medical practice in the United States, has become widespread and will almost certainly continue.

A second possibility which is not incompatible with the first, but which would further strengthen it is the creation of a new specialty *family medicine*. General practice is no longer possible because the great advances in medicine and surgery are too much for one man to learn or use well. It has the added disadvantage that

been put to a physician forty years ago Unfortunately the pediatrician magnificently trained to recognize and to treat severe life threatening disease through his hospital experience as an intern and resident, has not had the basic education in psychology to equip him to deal scientifically with the problems of behavior and learning which prove to be far more frequent and troublesome in his practice than the meningitis, diabetic acidosis, diarrhoeal dehydration or cardiac failure with which he became so familiar during his hospital years. Thus, the expectations and demands of the public with regard to medical care have broadened in scope and increased in amount faster than medical education has been able to adapt to these new needs.

While the bulk of our population has been involved in what amounts to an enormous shift into middle-class living in the suburbs, the 20–30% of our people who are poor many of them Negroes who have been displaced from farm labor in the southern United States, have gotten poorer and have become concentrated in the slum areas of our great cities. Here because of limited education during their rural childhood the parents have difficulty in obtaining any but the most menial unskilled jobs. Poorly paid often unemployed, ignorant of good health practices, crowded into the worst housing their maternal infant and tuberculosis mortality rates are much higher than average and the high incidence of family problems and social pathology further contributes to their miseries. Doctors entering practice settle in the suburbs where their patients can pay where living is pleasant and where the educational opportunities are best for their children. Consequent the poor in the cities, where good medi care is most needed, have fewer and few doctors available to them. Fortunatel free preventive services are provided the municipal departments of health wh the clinics of the great urban hospit provide treatment to all for acute illness but this gives a fragmented type of fam health care, rather than the comprehe sive care combining preventive and cu tive medicine which the family pediat cian offers to his wealthy well nourishe suburban families.

Thus on the one hand the scienti advances which have strengthened me cal education have limited the number doctors being trained, but increased th sophistication and skill in treating a preventing life-threatening diseases, whi on the other hand, the rapid rise in nu bers, in prosperity and in understanding health of the majority of our people ha enormously increased the demand for me ical services for those who can pay a the need for it among those who canno Because modern medicine is effective has become much more essential than t empirical medicine of the last centur Therefore we have a *quantitative* shorta of physicians because public expectatio have exceeded the rate at which they ha been produced.

But we also have a *qualitative* proble because even the doctors we have are n distributed in relation to the need f medical care since they are concentrate in the suburbs where health standards a highest and relatively few are in the gre urban centers where poverty overcrow ing and ignorance have created the grea est need. Finally even in the suburb

new knowledge through research, but to take responsibility for the study of the application of knowledge for the benefit of society even if it means considerable involvement in the life of the community. I believe this is a point of view that would have found favor with Socrates and his school.

it has less prestige, is more poorly rewarded than a specialty and thus tends to attract those with the poorest training. However, it is my belief that a group of physicians, trained properly to provide health and medical services to all members of a family or household, would fill a tremendous void in medical services in our country. These physicians should be specialists in people rather than in diseases. Their training should be as rigorous as for any other specialty. It should include pediatrics, internal medicine, psychiatry, epidemiology and preventive medicine. Their role would encompass diagnosis with their principal responsibility the determination of whether or not an illness was sufficiently serious to require referral to a specialist; treatment of acute minor illnesses and of chronic illness in conjunction with a specialist, preventive medical practices (immunization, nutrition, cancer detection, health education) and the handling of the multitude of anxieties, emotional disturbances and problems of adjustment which occur in families. One may ask how society can afford to have specialists in charge of the health of families. The answer, I believe, is twofold: first, they should be able to minimize serious illness, much of which is preventable; second, we must learn how to make more efficient use of all doctors, whose professional training requires so much time.

Consequently, a third possibility is to increase *the use of ancillary personnel in medical practice.* The nurse-midwife, the public health nurse, the social worker, the clinical psychologist, all of them skilled, but less trained than the physician, can, by working as a team under his direction multiply many fold the number of families he can care for competently.

Thus one might visualize medical and health services being provided in a community by a group practice of specialists, providing diagnostic and therapeutic services for specific diseases at a central hospital, closely allied with a group of specialists in family medicine, each of whom, assisted by a team of health workers, provides primary medical care to a large group of families. Such a scheme would combine the advantages of each of the three possibilities enumerated—group practice, family medicine and the use of ancillary personnel. This is obviously an idealized scheme and perhaps impractical. What is needed is research and experimentation in medical care conducted with as rigorous scientific standards as have been applied to biological research in the laboratory, so as to provide the knowledge which will permit medical practice to evolve in a way that will most effectively meet the health needs of the people in their particular culture.

Another essential responsibility of medical education, in this day of rapid scientific progress and constant change, is the continuing education of all physicians in practice. With much of his education becoming obsolete within a few years after completion of medical school and hospital training, the practicing physician must have the opportunity to study recent advances in his field at periodic intervals.

These are some of the challenges which face medical education in our country at this time. I believe it is the task of a university not only to preserve and hand on knowledge from the past and to provide

bator enables us to remo e protective clothing and thus makes possible better observation of the infant in the first critical days of life. Modern incubators moreover have devices for increasing the percentage of oxygen in the gas mixture the child is breathing. The introduction of modern incubators has surely improved the prognosis of the newborn infant with a low birth weight. However these apparatuses have some disadvantages. Careful investigations and catheterization of the umbilical arteries or vein, for instance are difficult to perform. Moreover the child may lose energy in an incubator by infra-red radiation. This is especially the case when the incubator is placed in a room with relatively cold walls and windows. Infections of incubators, especially of humidizing systems, with drug resistant micro-organisms (pseudomonas aeruginosa) have been reported from different hospitals. Modern incubators with an electric heating system are difficult to sterilize.

In the University Hospital of Groningen we try to avoid these difficulties by keeping infants with a low birth weight in a room with a constant temperature of 32° This temperature is only one or two degrees lower than the neutral temperature of most infants born with a low birth weight. A napkin is, in most cases, enough cover to keep the body temperature constant and the metabolic rate near that at the neutral temperature of the child. Care should be taken to avoid heat losses by infra red radiation, since greater parts of the infants skin are not covered at all. In our nursery an electric heating system in the ceiling keeps the temperature of the ceiling and part of the walls at about 40°C thereby preventing heat losses by infra red radiation. This electric heating system is used to keep the room temperature constant. *Most of the heat, however* is supplied by a usual central heating system. Air is blown into the room from outside and is electrically heated as it enters the room. Because the air in our town is not heavily poluted, we have no special system for cleaning the air nor do we have a complicated system to regulate the humidity The Dutch climate being humid, it is sufficient to mop the floor of the nursery twice a day to keep the relative humidity in the room at about 60 %. A higher degree of humidity is not likely to have great advantages, mainly because in many cases we give early intravenous fluids to the child, thus *compensating for water losses by respiration.* On the contrary a constantly high degree of humidity increases the risk of abundant growth of micro-organisms. Moreover a higher degree of humidity at this temperature makes work in the rooms for doctors and nurses difficult. With a relative humidity between 50 % and 60 % the heat in the premature unit is not felt to be oppressive by those working there provided there are facilities for taking a shower and changing clothes. With our system the possibilities for observation and investigation are better and the number of infections has decreased after the new system has been introduced. An additional advantage is that the nursing work in such a unit is less time-consuming. We now have two units in which 12 prematures are treated. The total number of nurses necessary is on the average 6.5 Each nurse works 40 hours a week. Therefore, at daytime two nurses and at night one are available for 12 infants

A Premature's Nursery without Incubators

by J. H. P. JONXIS

Compared with the adult, the newborn has a large body surface. This, together with the thinness of his skin and subcutaneous fat layer, is why his heat loss is considerably greater per kg of body weight than that of the adult. To keep his body temperature constant, his metabolic rate has to increase much faster than that of the adult as soon as the environmental temperature falls below the neutral temperature. The newborn at term and even the premature responds to a colder surrounding by a rise in oxygen consumption. This rise is, however, compared with that which occurs in the older individual, not large enough to compensate for the heat losses. Even a relatively small drop in the environmental temperature soon causes a drop in the body temperature although there is an initial rise in oxygen consumption. At first, only the temperature in the outer layers of the body drops. The temperature of the central parts of the body are kept as long as possible within the normal range. In a primitive society in which no possibilities exist in the form of clothes or fire to keep the child warm, heat produced by the human body is the only way of preventing a drop in temperature of the newborn. The first primitive beings, in the time before the invention of body protection against cold with hides or leaves and before fire came into use, must have lived in a tropical country in which even at night the temperature did not drop regularly below 30°C; otherwise the newborn would not have survived. Today clothes and heating are available to prevent larger heat losses in the newborn child and life in primitive groups is possible even under arctic conditions (Eskimos).

Special care is needed, however, to keep the body temperature of infants with a low birth weight constant. The body surface of these infants is per kg body weight still larger than that of the child born at term. Moreover, their metabolic response to cold is less pronounced than that of an infant with a normal birth weight. The neutral temperature, that is the temperature at which the metabolism is lowest, is in these infants a few degrees higher than that in the infant born at term. Protection against cooling with clothes and eventually hot water bottles is usually not sufficient to keep their body temperature constant. Therefore, such children are placed in boxes or incubators in which the temperature is kept constant at a level close to the neutral temperature of the child. This high environmental temperature in the incu-

bator enables us to remove protective clothing and thus makes possible better observation of the infant in the first critical days of life. Modern incubators moreover have devices for increasing the percentage of oxygen in the gas mixture the child is breathing. The introduction of modern incubators has surely improved the prognosis of the newborn infant with a low birth weight. However these apparatuses have some disadvantages. Careful investigations and catheterization of the umbilical arteries or vein, for instance are difficult to perform. Moreover the child may lose energy in an incubator by infra-red radiation. This is especially the case when the incubator is placed in a room with relatively cold walls and windows. Infections of incubators, especially of humidifying systems, with drug resistant micro-organisms (pseudomonas aeruginosa) have been reported from different hospitals. Modern incubators with an electric heating system are difficult to sterilize.

In the University Hospital of Groningen we try to avoid these difficulties by keeping infants with a low birth weight in a room with a constant temperature of 32° This temperature is only one or two degrees lower than the neutral temperature of most infants born with a low birth weight. A napkin is, in most cases, enough cover to keep the body temperature constant and the metabolic rate near that at the neutral temperature of the child. Care should be taken to avoid heat losses by infra red radiation, since greater parts of the infants skin are not covered at all. In our nursery an electric heating system in the ceiling keeps the temperature of the ceiling and part of the walls at about 40°C, thereby preventing heat losses by infrared radiation. This electric heating system is used to keep the room temperature constant. Most of the heat, however is supplied by a usual central heating system. Air is blown into the room from outside and is electrically heated as it enters the room. Because the air in our town is not heavily poluted, we have no special system for cleaning the air nor do we have a complicated system to regulate the humidity. The Dutch climate being humid, it is sufficient to mop the floor of the nursery twice a day to keep the relative humidity in the room at about 60 %. A higher degree of humidity is not likely to have great advantages, mainly because in many cases we give early intravenous fluids to the child, thus compensating for water losses by respiration. On the contrary a constantly high degree of humidity increases the risk of abundant growth of micro-organisms. Moreover a higher degree of humidity at this temperature makes work in the rooms for doctors and nurses difficult. With a relative humidity between 50 % and 60 % the heat in the premature unit is not felt to be oppressive by those working there provided there are facilities for taking a shower and changing clothes. With our system the possibilities for observation and investigation are better and the number of infections has decreased after the new system has been introduced. An additional advantage is that the nursing work in such a unit is less time-consuming. We now have two units in which 12 prematures are treated. The total number of nurses necessary is on the average 6.5 Each nurse works 40 hours a week. Therefore, at daytime two nurses and at night one are available for 12 infants.

Perhaps it is worth mentioning a few additional points When extra oxygen is needed by infants with a low arterial oxygen saturation a small oxygen tent is used. A very small premature may need a higher environmental temperature than our room temperature (32°C) to keep his body temperature constant By placing a perspex bell over the child the temperature in the bell rises about two degrees over the room temperature This is caused by heat production in the child and infra-red radiation from the electric heating system in the ceiling In a few exceptional cases a special perspex bell is used in which the temperature is kept constant by circulating water with the required temperature. When perspex bells are used, air eventually oxygen, is blown inside at a speed of 1 l per minute. For better observation and treatment the doctor and nurse should have free access to the child. To achieve this the incubator should have the size of a room

Glucose 6 Phosphate Dehydrogenase Deficiency in Female Heterozygotes and the X Inactivation Hypothesis

by CHRISTOS A. KATTAMIS

During the last decade an enormous literature about the many aspects of G-6-PD deficiency has been published [4, 17]. It was recognised from the very beginning that heterozygotes for G-6-PD deficiency may have normal, intermediate or very low levels of enzyme activity. Originally in a study of 6 mothers known to be heterozygotes by pedigree analysis, Childs et al [7] found 4 normal, 1 intermediate and 1 grossly deficient, in respect to GSH instability. Similarly Sansone [22] reported that of 10 heterozygote mothers of deficient males, 3 were normal, 4 intermediate and 3 deficient. Our own results with the GSH stability test in 44 mothers of male patients with favism revealed 10 normal, 30 intermediate and 4 deficient [26]. Quantitative G-6-PD determinations in 89 mothers of deficient males disclosed that levels of activity were normal in 13, grossly deficient in 10 and intermediate in 66 [12]. In these studies homozygote females had not been excluded by complete genetic studies.

For a long time the wide variation in enzyme activity in heterozygotes remained unexplained. Recently however the X inactivation hypothesis advanced by Lyon [16] offered an explanation for these findings which in turn are strong evidence that X inactivation does occur in the human female.

In the present communication data are presented on G-6-PD activity in heterozygotes detected by pedigree analysis and investigated by a combination of laboratory methods. An interesting pedigree is reported, in which enzyme activity is characteristic of the variations encountered in heterozygote females. This family was detected during the investigation of 68 other families. Finally these observations are discussed in relation to Lyon's hypothesis.

Material and Methods

76 female heterozygotes detected by careful pedigree analyses of G-6-PD deficient families were studied. A female was considered to be a true heterozygote if

(i) She was the mother of a deficient male and had either a normal son or a normal father.
(ii) She was the daughter of a deficient father and had either a son or a mother and brothers who were normal.
(iii) She was born to a homozygote mother and a normal father.

Thus all females homozygotes were excluded.

G-6-PD activity was investigated by the

TABLE 1 *Standards of our laboratory for the methods employed in the study*

Methods	Range		
	Normal	Intermediat	Grossly deficient
B.C.B. decolorization (time in min)	30–60	60–150	> 150
G-6-PD activity (units per 100 ml/PRC)	180–520 (394 ± 61)	40–280	0–40
Methemoglobin reduction (screening test)	0	0–+ + +	+ + + +
Cyanmethemoglobin elution technique (percentage of normal cell)	95–100	6–95	0–5

B.C.B. = brilliant cresyl blue. PRC = packed red cells)

brilliant-cresyl blue (B.C.B.) decolorization test [12, 18] the quantitative measurement of G-6-PD activity [8, 1., 27], the combined methemoglobin reduction test (screening test) [5] and the cyanmethemoglobin elution technique [15]

By the last method two distinct red cell populations can be identified in most heterozygotes, one consisting of stained cells with normal activity (Fig 3a) and another consisting of unstained cell ghosts with grossly deficient activity (Fig 3b)

Table 1 summarizes standards of the four methods in our laboratory Normal values for G 6-PD activity have been obtained from 100 normal males [12].

Results

Female heterozygotes

The results of G-6-PD activity in heterozygotes have been summarized in Table 2 Figure 1 illustrates G 6-PD activity in all heterozygotes studied. It can be seen that it ranged from 0–520 units/100 ml of packed red cells i.e. from total absence to normal Fifty two (69.3 %) had intermediate values, ranging between those of grossly deficient males (< 10 % of the normal mean) and those of low normal (> 80 % of the normal mean); five (7 %) had very low and 18 (24 %) had normal activities It is of particular interest that of 18 heterozygotes with normal activity 13 had very low normal levels, and in only 5 was the activity at or above the normal mean Thus heterozygotes with rather high normal activity were *very few* and so were those with complete enzyme *deficiency*

The cyanmethemoglobin elution technique proved very helpful in differentiating the two red cell populations in heterozygotes with intermediate G 6-PD values. *On the contrary* we found it very difficult or even impossible to predict heterozygotes with normal enzyme activity The validity of this method and the discrepancies observed have been already discussed by others [6 21]

Pedigree analysis

The results of the biochemical investigation of all members of the *G-6-PD* deficient family are clearly illustrated in Fig 2. Numbers indicate units of *G-6-PD* activity per 100 ml of packed red cells and numbers in parenthesis the percentage of deficient cells by the cyanmethemoglobin elution technique

In this family the deficient grandfather (I_1) gave birth to 3 daughters who were expected to be heterozygotes. However

TABLE 2. *G-6-PD activity in 75 heterozygote females tested by four methods*

Methods	Total No. cases	Normal N	Normal %	Intermediate No.	Intermediate %	Grossly deficient No.	Grossly deficient %
B.C.B. decolorisation	75	39	51.9	26	34.5	10	13.3
Methaemoglobin reduction (screening test)	75	19	25.3	48	63.6	8	10.7
Cyanmethaemoglobin elution technique	5	25	33.3	43	57.3	7	9.3
Quantitative G-6-PD determination	75	18	24.0	52	69.3	5	7.0

biochemical investigation revealed that G-6-PD activity in the first daughter (II_2) was within the normal range (388 units/100 ml) with 100% stained erythrocytes (Fig. 3a); the second daughter (II_3) was totally deficient with 100% unstained erythrocytes, and the third (II_4) had intermediate levels of activity (208 units/100 ml) and 70% of unstained erythrocytes.

The same variation in G-6-PD activity was observed in the third generation. II_4 who was completely deficient gave birth to 3 heterozygote girls in whom G-6-PD activity was respectively 0, 120, and 230 units/100 ml of packed red cells.

Pedigree analysis also shows that II_4 and III_5 were not homozygotes since the first had two normal sons, and the second a normal father.

This pedigree illustrates very clearly the wide range of G-6-PD activity in female heterozygotes, derived from the same ancestor.

Discussion

In 1960 Ohno & Hauschka [20] demonstrated that the two X chromosomes in females of various mammalians were different, one resembling the autosomes, the

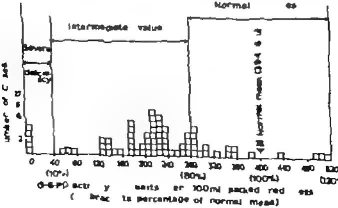

Fig. 1. G-6-PD activity in 75 female heterozygotes detected by pedigree analysis.

other being hyperpyknotic and forming the sex-chromatin body. This observation led Lyon [16] to suggest that the hyperpyknotic X-chromosome is genetically inactive that inactivation takes place early in embryonic development and that the progeny of each cell show the same pattern of inactivation.

At present the evidence that one of the X chromosomes is inactivated in the normal human female is incomplete although for some loci of the X-chromosome the evidence is very strong [25]. Accumulating data on G 6-PD deficiency confirm, directly or indirectly that the theory of X inactivation may be nicely applied to the sex linked locus of glucose-6-phosphate dehydrogenase. This locus has already been used as a genetic marker in studies on X chromosome inactivation in the normal human female [1 2].

Originally it was demonstrated that the methemoglobin reduction rate and the reduced glutathion stability test in erythrocytes from females heterozygous for G 6-PD deficiency followed a two com

Fig. 3. Results of the cyanmethemoglobin elution technique in three heterozygotes of the pedigree (a) stained cells with normal enzymic activity II_2. (b) Unstained (ghost) cells with total absence of activity II (c) Two populations of normal and deficient cells in heterozygote with intermediate levels of activity II_4

ponent curve closely resembling that obtained from mixtures of normal and deficient cells [2]. Later G-6-PD deficient erythrocytes were separated from the normal cells in a female heterozygous both for G-6-PD deficiency and sickle-cell anemia, the enzymic activity of the deficient cells was shown to be very similar to that of G-6-PD deficient male. These findings were suggestive of the presence of two red cell populations [3].

Red cell mosaicism in the female heterozygote was also confirmed, rather directly by other methods. In most heterozygotes two red cell populations can be demonstrated by the quantitative cyanmethemoglobin elution technique, one with normal, the other with grossly deficient activity [23, 24]. Decreased enzymic activity with evidence of cell mosaicism has also been observed in skin cultures from heterozygotes [10]. Cloning in these cultures from heterozygotes has confirmed beyond any doubt the presence of two types of cells, i.e., clones with normal and clones with low enzyme activity [9]. Till now no serious evidence has been presented against cell mosaicism in female heterozygous for G-6-PD deficiency [4]. In the light of these observations an explanation for the greatly varying expression of G-6-PD activity in heterozygotes is no longer impossible. It has been shown in the present investigation that in heterozygotes detected by detailed pedigree analysis excluding all probable homozygotes, enzyme activity ranged from complete absence to entirely normal levels. In 7.0% there was complete absence or very low activity corresponding to that of deficient males or homozygotes with the Caucasian type of the deficiency usually encountered in Greece [8, 11, 12, 19]. In 89.3% values were intermediate and in 4% normal.

In this investigation it has also been confirmed by the cyanmethemoglobin elution technique that most females with intermediate levels of G-6-PD activity had two red cell populations, one normal, the other resembling that of deficient males. With very few exceptions the percentage of each of cell population was proportional to the level of enzyme activity. A uniformly normal cell population was found in heterozygotes with normal enzyme activity and a uniformly deficient population in grossly deficient heterozygotes. The presence of very few (<5%) deficient cells in the former or normal cells in the latter does not, in our opinion, indicate heterozygosity. These findings also show that heterozygotes cannot all be detected by the laboratory methods available.

Complete pedigree analysis may prove to help considerably in determining the genotype of a female heterozygote [13, 14]. The pedigree reported in this study appears to be unique in that it demonstrates great variations in the expression of G-6-PD activity in heterozygotes belonging to the same family. Intermediate levels in heterozygotes are to be expected as a result of the dosage effect of the mutant gene. What was really puzzling was the considerable proportion of heterozygotes with either normal or extremely low enzyme activity.

These findings indicate that enzyme activity in heterozygotes depends upon the ratio of normal to deficient red cells. This ratio is probably related to the proportion of progenitor cells in which a

normal or a deficient X chromosome has been inactivated. The X chromosome appears to be inactivated at a very early stage of development when only a very small number of cells, perhaps 3 or 4 serve as progenitors [2, 16]. The inactivated X-chromosome is replicated with every cellular division but remains inactive during interphase. It follows then that in a female heterozygote the normal allele will be expressed in some body cells and the deficient allele in others. Variations in enzyme activity of the female may be explained by the very fact that the X-chromosome is inactivated in a limited number of progenitor cells; considering that X inactivation is random in some heterozygotes the precursors of the erythroid series may be all expected to contain by chance the X chromosome bearing the inactivated normal gene. The entire erythroid series would consist of cells with the mutant gene for G-6-PD activity and heterozygotes would be completely deficient with only one population of deficient cells. Similarly heterozygotes with normal G-6-PD activity may result from inactivation of the X-chromosome bearing the mutant gene in all progenitor cells. In heterozygotes with intermediate levels of activity and two red cell populations inactivation may have occurred of the normal X-chromosome in some progenitor cells and of the mutant X-chromosome in others. A mosaic with two cell populations would be thus produced. G-6-PD activity in these cases would depend upon the ratio of inactivated normal to mutant X-chromosomes; and since inactivation is merely a matter of chance it is evident that in the majority of heterozygotes values of G-6-PD activity will be intermediate and that there will be a wide individual variation in the intermediate values.

Summary

The levels of G-6-PD activity in all female heterozygotes detected by pedigree analysis are reported together with biochemical and genetic data of a pedigree in which a wide variation in G-6-PD activity was revealed in heterozygotes. The results strongly favour the hypothesis that one X chromosome is inactivated during early embryonic development in the human female at least as far as the locus of G-6-PD is concerned.

normal or a *deficient* X-chromosome has been inactivated. The X chromosome appears to be inactivated at a very early stage of development when only a very small number of cells, perhaps 3 or 4 serve as progenitors [2, 10]. The inactivated X chromosome is replicated with every cellular division but remains inactive during interphase. It follows then that in a female heterozygote the *normal* allele will be expressed in some body cells and the deficient allele in others. Variations in enzyme activity of the female may be explained by the very fact that the X chromosome is inactivated in a limited number of progenitor cells; considering that X inactivation is random in some heterozygotes the precursors of the erythroid series may be all expected to contain by chance the X chromosome bearing the inactivated normal gene. The entire erythroid series would consist of cells with the mutant gene for G-6-PD activity and heterozygotes would be completely deficient with only one population of deficient cells. Similarly heterozygotes with normal G-6-PD activity may result from inactivation of the X chromosome bearing the mutant gene in all progenitor cells. In heterozygotes with intermediate levels of activity and two red cell populations inactivation may have occurred of the normal X chromosome in some progenitor cells and of the mutant X-chromosome in others. A mosaic with two cell populations would be thus produced. G-6-PD activity in these cases would depend upon the ratio of inactivated normal to mutant X-chromosomes, and since inactivation is merely a matter of chance, it is evident that in the majority of heterozygotes values of G-6-PD activity will intermediate and that there will be a wi individual variation in the intermedia values.

Summary

The levels of G-6-PD activity in a female heterozygotes detected by pedigre analysis are reported, together with bio chemical and genetic data of a pedigree i which a wide variation in G-6-PD activity was revealed in heterozygotes. The results strongly favour the hypothesis that one X-chromosome is inactivated during early embryonic development in the human female at least as far as the locus of G-6-PD is concerned.

mg/100 ml, 4.7 mg free 6.5 mg conjugated. Serum alkaline phosphatase was 25.0 King Armstrong units/100 ml; flocculation tests were negative. The serum G O T was 55 K units/ml and the G.P T 25 K units/ml. Urine was strongly positive for bile, but was free from protein. The total urinary catecholamines were *80 μg/100 ml* (1.2 μgm/mg of creatinine) and the V.M.A. was 244 μgm/100 ml (5.4 μgm/mg of creatinine), both these figures being within normal limits. Lumbar puncture produced yellow fluid under normal pressure. Queckenstedt's test was negative. The fluid contained 400 mg of protein/100 ml with a positive globulin test. C.S.F sugar was 72 mg/100 ml. Very few cells were present. Chest and skeletal X-ray showed no abnormality and abdominal lymphangiography showed that the glands which were opacified were of normal size and architecture. However examination under anaesthesia whilst the lymphangiogram was being performed revealed a number of very large glands and these did not fill at all with the radio-opaque medium. Biopsy of a cervical lymph node showed a proliferating mass of lymphocytes with invasion of the capsule and surrounding tissues and many mitotic figures.

The diagnosis was therefore generalised lymphosarcoma with obstructive jaundice probably due to gland pressure at the porta hepatis; compression paraplegia due to lymphosarcomatous involvement of the lepto-meninges.

Despite the widespread disease it was thought that the patient's general condition was good enough to justify a trial of chemotherapy in the hope of producing some palliation. He was started on treatment with Vincristine the first dose being 0.05 mg/kg intravenously and Prednisolone 10 mg 3 times daily. Further doses of Vincristine were given at weekly intervals, the increment being 0.025 mg/kg for each dose. In the next two weeks the jaundice decreased, the serum bilirubin falling to 5 mg/100 ml, and he began to have slight movements *of his legs*. One month after starting treatment he developed a swelling on the anterior aspect of the tibia and X-ray showed marked destructive changes at this area. At this time, jaundice was very much less and there was considerable increase of the amount of voluntary movement in the lower limbs.

Six injections of Vincristine at weekly intervals were given after which he was started on Cyclophosphamide 30 mg daily by mouth; Prednisolone was gradually reduced. *He then developed a firm swelling of* the left mandible which rapidly increased, involved the gums and produced loosening of a number of teeth. Although there had been further improvement in muscular power of the lower limbs, he was still unable to stand and there was no subsequent improvement. Over the next few weeks he developed further neurological signs including proptosis of the right eye, left facial paralysis and bilateral sixth nerve paralysis. Rapid growth of tumour on the other side of the mandible made it difficult for him to eat, although he was still quite conscious and cheerful. Local radiotherapy to the jaw produced some improvement. Despite all these complications he was able to be discharged home after 2½ months in hospital and he had a comfortable month at home before his final admission in coma and his death shortly afterwards.

At post mortem examination the main findings were the deposits in the mandible an enlarged lymph node below the left kidney and a few sites of previous disease in lymph nodes represented by shrunken yellowish-brown areas. Deposits were present in the dura and there was diffuse thickening of the lepto-meninges over the base of the brain, extending along the cranial nerves and of the spinal cord meninges with the emerging nerves.

2. *Lymphosarcoma*

R. J was 18 months old when he was first admitted to hospital. He had been ill at home for a month with obstructive jaundice and during the 2 weeks before admission he had had occasional haematemesis and melaena.

Acta Paediatrica Scandinavica, Supplement 172 1967

From the Alder Hey Children's Hospital, Liverpool Head S E Keidan, Consultant Paediatrician

Paraplegia in Childhood Malignant Disease

by †S. E. KEIDAN

It is a great honour to be asked to collaborate in paying tribute to the memory of Professor Choremis whose sudden death was so great a loss to Paediatrics in Greece Although Professor Choremis was a distinguished scientific investigator he was primarily a clinician, trained in the great European tradition of clinical paediatrics and perhaps it is as a disciple of Aesculapius and a spiritual descendant of Hippocrates rather than as a scientist that he would wish to be remembered

I was privileged to meet him on only one occasion, during a brief visit that I paid to Athens in 1965 During the course of our discussion I learnt of his interest in the problem of malignant disease in childhood and, when I was asked to contribute to this memorial volume I thought that a clinical article on this theme might be appropriate The following report deals with 5 children with various types of malignant tumour who developed paraplegia in the course of their illness as a result of infiltration of the spinal canal with tumour the tumour having originated in some other part of the body All tumours, both primary and secondary of the spinal cord and appendages are uncommon in children and paraplegia resulting from secondary malignant disease seems to be particularly uncommon. With increasing awareness of malignant disease and its manifestations in childhood this complication may be recognized more frequently in the future and in some cases it may be amenable to treatment which, although only palliative may nevertheless be worth while

Case Reports

1 *Lymphosarcoma*

A 3-year-old boy complained of pain in the shoulders and upper arms and a few weeks later developed a swelling on the right side of his neck. Jaundice developed and gradually deepened A few days before admission to hospital he became unable to move his legs.

On examination he was very ill and deeply jaundiced The liver was enlarged 10 cm below the costal margin, the spleen was just palpable and enlarged lymph nodes could be felt in the abdomen The right cervical lymph nodes were greatly enlarged. He was unable to perform any voluntary movements of his lower limbs but although they were quite flaccid, the ankle and knee jerks were both very brisk and the plantar responses were extensor He was a very fretful, apprehensive child and it was difficult to be sure if there was any associated sensory loss.

On investigation his peripheral blood showed a normal haemoglobin and leucocyte picture The total serum bilirubin was 11-

entirely disappear. Two months later she complained of dizziness and the papilloedema increased. This time she was treated with intrathecal hydrocortisone 10 mg per dose for 3 doses. As this produced no improvement, a fourth course of intrathecal Methotrexate was given, 5 doses in all. She remained unwell and papilloedema steadily increased. As blast cells had reappeared in the C. S. F. a fifth course of intrathecal Methotrexate was given. By now there was also evidence of haematological relapse. Over the next few weeks she developed increasing weakness of her legs progressing to almost complete flaccid paralysis with absence of the tendon jerks in the lower limbs. She was given irradiation to the occiput and the whole spine and within a few weeks she was able to stand and walk again, but the tendon reflexes were slow to return. Improvement was brief and within a few weeks the paraplegia recurred. Further radiotherapy was not advised and so a sixth course of intrathecal Methotrexate was given. Despite the evidence of cord infiltration, the C. S. F. pressure showed a free rise and fall and there was no evidence of a block. Improvement occurred for a few weeks, but signs soon returned and she now had evidence of widespread neurological involvement. There was a left facial paralysis, marked weakness of the right arm and flaccidity [illegible] both lower legs with absence of tendon reflexes. No further active treatment was justified.

4. *Wilms' tumour*

J. S. was first seen shortly before his second birthday. About 2 months previously his mother had noticed enlargement of his abdomen. Some weeks later he developed marked thirst, especially at night time. A month before his first attendance he had been on a visit to New York City with his parents and whilst there he had had a feverish illness. He was diagnosed as having an upper respiratory infection and treated with an antibiotic. On return from the United States he was referred because of increasing enlargement of his abdomen.

The main finding on examination was a large, rounded fixed mass in the left loin. Intravenous pyelography showed marked dilatation of the calyces and of the renal pelvis with generalised enlargement of the left kidney. At laparotomy there was a huge tumour which was adherent to the spleen. It was removed with some difficulty and the spleen was also removed at the same time. The neighbouring glands were not enlarged, but a number were removed for section. They did not show histological evidence of invasion. The renal tumour was confirmed as a Wilms' tumour. Two days before operation he had been started on treatment with Actinomycin D in daily dosage of 12 μgm/kg intravenously. It was planned to give a 10 day course, a total dosage of 120 μgm/kg, but on the ninth day his platelet count suddenly fell from 270,000 per cmm to 90,000 per cmm and treatment was stopped. Over the next few days platelets continued to decrease and he developed extensive purpura of the abdominal wall. He also had glossitis and a macular rash on his lower limbs. He was treated with Prednisolone, 10 mg 3 times daily for a few days and the platelet count rapidly rose.

For the next 6 months he remained very well and regular clinical and radiological examination showed no abnormality. He then developed increasing proptosis of the right eye due to a rapidly growing retro-ocular metastasis. Pain in the abdomen and lower back developed and became increasingly severe. Transient relief was produced by radiotherapy. Loss of power in the legs was first noticed about this time; it gradually increased until he had complete paraplegia of the lower limbs. Sensation was also affected until eventually he had complete anaesthesia of the lower limbs and of the lower abdominal wall. Shortly before this, his abdominal and low back pain had become so severe and was so resistant to analgesic and narcotic drugs that intrathecal injection of phenol was seriously considered. The advent of complete anaesthesia served the same end by producing complete relief of this pain. The subsequent steady deteriora-

On examination he was wasted deeply jaundiced and had dilated veins over the lower chest The abdomen was distended with signs of free fluid A large firm mass was palpable in the right upper abdomen.

At laparotomy a large retroperitoneal tumour was discovered lying mainly under the duodenum and involving its posterior wall It also intimately involved the inferior vena cava and the portal vein Because of its adherence it proved impossible to remove The gall bladder was very distended and, as there was obstruction to the outflow of bile it was anastomosed to a loop of the small intestine A gastroenterostomy was also performed to bypass the tumour

After operation the jaundice rapidly cleared A biopsy specimen proved to be normal pancreas only and it was obvious that this had been taken from the gland stretched tightly over the tumour As further exploration was clearly unjustifiable a precise diagnosis was not obtained

After operation he was referred for radiotherapy to the abdomen and treatment was given over 28 sessions with the maximum dose of 3,500 rads, minimum 3 430 rads of 230 kilovolt irradiation During the course of this treatment the abdominal tumour mass disappeared completely and his general condition improved However whilst improvement was occurring at one site he developed further evidence of disease. A right external rectus paralysis suddenly occurred and X ray of his skull showed multiple osteolytic areas. Deterioration in his general condition recurred and he soon became cachectic It was not thought justifiable to give any cytotoxic therapy but, as the primary tumour could possibly have been lymphosarcoma it was thought reasonable to treat him with corticosteroids in the hope of producing some temporary relief He was discharged home on Prednisolone 25 mg daily

His condition was so poor that it was not thought that he had more than a few days to live However when he was brought back to hospital outpatients 8 weeks later he was reported as being cheerful and having a good appetite. A new development, however was that he now had a complete flaccid paraplegia and was doubly incontinent. As his parents were managing to deal with the difficult nursing problem at home readmission was not advised and he died one week later.

Post mortem examination was not performed.

3 Acute leukaemia

D E. developed acute leukaemia when she was 4½ years old. She was treated with Prednisolone and 6-Mercaptopurine and full remission was obtained in a few weeks. After 7 months maintenance treatment with Mercaptopurine she showed signs of haematological relapse Treatment was changed to Methotrexate 5 mg daily but she soon developed stomatitis, diarrhoea and pancytopenia. Further steroid therapy was given and the Methotrexate was then resumed in dosage of 2.5 mg daily later reduced to 2.5 mg on alternate days. Eight months later she developed headache nausea and vomiting and had bilateral papilloedema. The C S F showed the presence of leukaemic blast cells and she was treated successfully with intrathecal Methotrexate. Three months later papilloedema recurred and blast cells were again found in the C. S. F Eleven further intrathecal injections with Methotrexate were given but although the C S F became clear papilloedema persisted. During the course of the second series of intrathecal injections she developed anaemia and thrombocytopenia. Further steroids were given and maintenance treatment was changed back to 6-Mercaptopurine During the ensuing months she had frequent signs of drug toxicity and intercurrent infection but no frank evidence of relapse Eight months after the second episode of neurological involvement she had recurrence of vomiting and papilloedema and the C S. F again showed the presence of blast cells. Eleven further intrathecal injections of Methotrexate were given with clinical improvement both in symptoms and in the degree of papilloedema although it did not

severe pain, the failure to improve with corticosteroids and Vinblastine all seemed very unusual for histiocytosis. Further skeletal X-rays were now done and they showed considerable progression of all the skeletal lesions. Some of them showed small areas of sclerosis as well as the osteolysis. Another biopsy was now taken from the iliac crest. The histological appearances were of highly malignant tumour destroying bone trabeculae. The tumour consisted of round cells with scanty cytoplasm, large nuclei and numerous mitoses. There was very little differentiation, but in places the arrangement was more compact. In other areas the cells appeared to be lining endothelial spaces. The appearances suggested a malignant sarcoma and the probable diagnosis was "Ewing's sarcoma. This diagnosis was much more in accord with the clinical events. As all efforts at treatment had failed to halt the progress of the disease but it had been possible to relieve her pain, she was discharged home where she died some weeks later.

Post mortem examination was not performed.

Discussion

In a review of the medical literature for the previous 10 years Hamby [4] in 1936 was able to collect 100 cases of tumour of the spinal canal in children. Most of these tumours were primary neural tumours of the cord. Of the small number which were unclassified or grouped as miscellaneous, only one appears to be a definite secondary tumour in that it is listed as a malignant renal tumour. In 1944 Hamby [5] reviewed the literature for the subsequent 10 years and found a further 114 tumours of the spinal canal in children. In this second list none appeared to be metastatic except possibly one listed as an "invasive fibroma. Chloroma is referred to in both series, there having been 8 cases in the first and 1 in the second, but it is not quite clear in the context as to whether this term is used specifically to indicate a locally invasive tumour which is "almost invariably accompanied by acute granulocytic leukaemia" [2]. In 1954 Svien, Thelen & Keith [7] reported 41 cases of intraspinal tumours in children which had been seen over a 20 year period at the Mayo Clinic. The majority of these were primary neural tumours. There had been one case of reticulum cell sarcoma and one lymphoblastoma. There were also two definite metastatic tumours, one from a carcinoma of the thyroid and the other from a Ewing's sarcoma of the sternum.

Paraplegia due to secondary malignant disease is certainly uncommon. In the index to the most recent edition of his authoritative textbook on *Diseases of the Nervous System in Infancy Childhood and Adolescence* Ford [3] lists over 40 causes of paraplegia, but secondary malignant disease is not among them. Presumably as it is more likely to occur at an advanced stage of the disease when the patient's general condition is deteriorating, it is less likely to be drawn to the attention of a neurologist. However on occasion paraplegia may be one of the presenting signs of illness as in Case 1 of the present report and, although in that case there were many other features which enabled a diagnosis to be established, the primary tumour or tumours may be less conspicuous and the patient could then be spared much unnecessary investigation and possible surgical intervention, if the possibility of secondary malignant disease were considered. However unlike cerebral secondaries in adults from undiagnosed bronchial or other primary tumours, all malignant tumours in

tion in his condition was unbearably slow and was made even more distressing by the development of pain above the anaesthetic area. Further metastases became evident including one in the lower jaw which eventually almost filled his mouth and made feeding very difficult. He died 8 months after the tumour was first diagnosed and 3 months after metastases had first become apparent.

5 *Ewing's sarcoma*

A 16 year old girl was referred to Alder Hey Children's Hospital with a history of backache which developed after a fall 18 months previously. The backache at first only lasted a few days, but recurred some months later when she also developed severe pain in the right hip. Skeletal X rays at that time were normal. The pain persisted and X rays one month later showed osteolytic areas in the right femoral neck and in both iliac crests. She was admitted to hospital for further investigation and by now pain became very severe requiring frequent injections of Pethidine. Further investigation at that time added little to the diagnosis. Her white cell count was 11,200 with 70% of polymorphs. The serum alkaline phosphatase was 10.0 K. & A units/100 ml, serum calcium was 9.4 mg/100 ml. Biopsy of one of the bony lesions over the right iliac crest produced yellowish brown, soft gelatinous material which on section, was thought to resemble eosinophilic granuloma of bone. She was treated with Prednisolone, Cyclophosphamide and Methotrexate, but there was no improvement and the pain continued to be severe. Over the next few months she developed increasing proptosis of the left eye.

At the time of admission to Alder Hey Hospital she looked ill and was in considerable pain. There was marked tenderness over the dorsal spine and over the lower ribs. Apart from the left proptosis there were no definite abnormal findings in the nervous system at this stage.

The severity of her pain was unusual for histiocytosis, but re-examination of the scanty histological material seemed to be just about compatible with this diagnosis and, as other forms of treatment had been ineffective she was started on Vinblastine 0.1 mg/kg intravenously increasing weekly up to 0.3 mg/kg. The day after the first injection of Vinblastine she was unable to move her left leg. The knee jerks were absent, the ankle jerks were present and the plantar responses were flexor. Sensation appeared normal. Within a few days there was complete loss of power in both lower limbs and she developed flexor spasms. The plantar responses were now extensor and she had complete anaesthesia of the lower parts of both limbs. She was unable to pass urine and the bladder could only be emptied by compression. At the time of admission to Alder Hey the margins of both optic discs had been slightly blurred but by now there was definite papilloedema. Because of this, it was thought advisable not to perform lumbar puncture. The neurological signs over the lower part of the body meanwhile progressed, so that she had total paresis of the body below the level of D5 and 6 and a sensory loss which was complete below this level.

Pain continued to be very severe and was difficult to control by analgesic drugs. Because of the rapid progression of the paraplegia she was referred for X ray therapy and a total dose of 500 r at the level of D2 to L1 were given through a narrow field. A few days after this, there was slight return of movement in the lower limbs. She showed a withdrawal reflex and slight voluntary movement could be produced. Improvement continued to occur and there was some return of sensation, but useful function was not regained. Meanwhile the swelling over the left eye became much more severe, pushing the eye forward to such degree that recurrent dislocation of the globe was occurring. As this was very distressing to the patient and staff tarsorrhaphy was performed. A small dose of local radiotherapy was also given to the orbit.

The rapid progression of the lesions, the

provement was produced by local radiotherapy but it was only of brief duration. The paraplegia soon recurred and was accompanied by more widespread signs of neurological involvement.

Lymphosarcoma has many affinities with acute lymphatic leukaemia and, in deed, about 20 % of cases of lymphosarcoma terminate with generalised leukaemia. The disease can, therefore be regarded, in many instances, as multicentric in origin and the widespread neurological involvement that occurred in Case 1 was not necessarily metastatic in the strict sense of the term. The evidence of cord compression occurred relatively early in the course of the disease. Although there was some improvement in the neurological signs and symptoms following the course of chemotherapy it was less than might have been expected judging by the improvement that occurred in other parts of the body. It is probable that irreversible damage had occurred to the spinal cord so that only a limited degree of improvement was possible.

So far as the management of paraplegia is concerned, this of course will depend to a considerable extent on the patient's general condition. If the primary disease itself is one that might be expected to respond temporarily to some method of treatment, as in leukaemia or lymphosarcoma, efforts should certainly be made to relieve the cord compression. Local radiotherapy is probably the treatment of choice in such cases although Svien, Th len & Keith [7] advised that laminectomy should be done to relieve the compression to the cord immediately as they think that the slower response to radiotherapy and irradiation itself may produce direct injury to the cord. Laminectomy was not performed in any of the cases in the present series and it is doubtful whether it would have been justifiable in the particular circumstances reported here. The two patients who were treated with local radiotherapy certainly showed some improvement, rapid in the child with leukaemic compression of the cord and much slower in the girl with Ewing's sarcoma. In the other three children the disease was so far advanced that it was not thought justifiable to put them to the discomfort of radiotherapy. In such cases symptomatic management is all that can be done. This includes attention to bladder function, as a distended bladder can give rise to considerable discomfort. At first it may be possible to empty the bladder by regular manual expression. Otherwise the insertion of long indwelling catheter connected directly to a sterile receiver will keep the bladder empty and minimise the risk of infection. If the cord lesion is above the lumbar segments, automatic bladder function may return so that when the bladder is distended to a certain point, it will be emptied in a single act of micturition either spontaneously or on stimulation of the skin of the perineum. If the lesion is in the lumbosacral region, the automatic bladder will not develop although the bladder may regain some tone. Constipation from lack of rectal sensation and from loss of tone in the muscles of defecation may be controlled by small volume enemas although occasional manual removal of faeces may also be needed. Trophic ulceration of the skin may be very troublesome in the early phase of paraplegia. Frequent gentle turning of the patient and careful nursing attention to

children are so relatively uncommon that it is obviously more difficult to maintain the same high index of suspicion.

The spinal cord may be compressed by direct invasion of tumour from without or by blood borne metastatic growths. According to Willis [8] direct invasion of the cord except as microscopic perivascular extension, is unusual It probably occurred however in Case 4 where the spread was directly from the abdomen through the vertebral foramina Abdominal pain and pain in the back preceded the paraplegia and the pain was so severe that chemical destruction of the sensory nerve roots by phenol injections was seriously considered, but was anticipated by subsequent neoplastic destruction of those same roots with complete relief of pain and with the onset of complete anaesthesia Direct spread of tumour probably also occurred in Case 5 Here the secondary tumour was in the vertebrae at the earlier stage when back pain and tenderness were present When the spinal canal became invaded, events moved rapidly so that within a few days of developing weakness in one leg she had a complete paraplegia below the level of D5 and 6 with sensory loss and paralysis of the sphincters. In Case 2 the histological diagnosis was never established. When he was first seen, a posterior abdominal tumour was present and this could have spread to the cord by direct extension However the main tumour mass shrank rapidly during treatment by radiotherapy and there was no evidence of cord involvement at that time When the paraplegia developed some time later there was evidence of metastatic spread elsewhere in the body as shown by the presence of deposits in the skull and it is more likely that the cord compression was due to blood borne metastases rather than to direct spread.

Willis [8] states that secondary tumours of the cord are usually due to blood-borne metastases and that these may be less rare than is supposed but they do not often give rise to clinical symptoms of disease and so they may not always be sought for in routine post mortem examination. In most cases with metastases in the spinal cord multiple cerebral metastases are present as well and these will probably dominate the clinical picture.

The question as to whether focal deposits of cells in the leukaemias should be regarded as metastases has previously been debatable but is largely an academic question Recent studies, such as those of Mathé and others [6] have confirmed that widespread tissue infiltration is a common finding in leukaemia even when the disease appears to be in complete remission. Involvement of the central nervous system is particularly common and has been reported in as many as 30 % of some series of cases. It usually manifests itself by a rise in intracranial pressure with headache, vomiting and papilloedema as the predominant findings. Cranial nerve palsies and convulsions are less common. Signs and symptoms due to compression of the spinal cord are much less common. Ford [3] describes one case of compression of the spinal cord by an extradural mass in a child with acute leukaemia, the mass being composed of leukaemic cells. In Case 3 of the present report there were repeated episodes of neurological involvement but towards the end the cord symptoms were predominant. Considerable im-

rovement was produced by local radiotherapy but it was only of brief duration. he paraplegia soon recurred and was ccompanied by more widespread signs of eurological involvement.

Lymphosarcoma has many affinities rith acute lymphatic leukaemia and, in leed, about 20% of cases of lymphosarcoma terminate with generalised leukaemia. The disease can, therefore, be regarded, in many instances, as multicentric in rigin and the widespread neurological nvolvement that occurred in Case I was not necessarily metastatic in the strict sense of the term. The evidence of cord compression occurred relatively early in the course of the disease. Although there was some improvement in the neurological signs and symptoms following the course of chemotherapy it was less than might have been expected judging by the improvement that occurred in other parts of the body. It is probable that irreversible damage had occurred to the spinal cord so that only limited degree of improvement was possible.

So far as the management of paraplegia is concerned, this of course will depend to a considerable extent on the patient's general condition. If the primary disease itself is one that might be expected to respond temporarily to some method of treatment, as in leukaemia or lymphosarcoma, efforts should certainly be made to relieve the cord compression. Local radiotherapy is probably the treatment of choice in such cases although Svien, Thelen & Keith [7] advised that laminectomy should be done to relieve the compression to the cord immediately as they think that the slower response to radiotherapy and irradiation itself may produce direct injury to the cord. Laminectomy was not performed in any of the cases in the present series and it is doubtful whether it would have been justifiable in the particular circumstances reported here. The two patients who were treated with local radiotherapy certainly showed some improvement, rapid in the child with leukaemic compression of the cord and much slower in the girl with Ewing's sarcoma. In the other three children the disease was so far advanced that it was not thought justifiable to put them to the discomfort of radiotherapy. In such cases symptomatic management is all that can be done. This includes attention to bladder function, as a distended bladder can give rise to considerable discomfort. At first it may be possible to empty the bladder by regular manual expression. Otherwise the insertion of long indwelling catheter connected directly to a sterile receiver will keep the bladder empty and minimise the risk of infection. If the cord lesion is above the lumbar segments, automatic bladder function may return so that, when the bladder is distended to a certain point, it will be emptied in a single act of micturition either spontaneously or on stimulation of the skin of the perineum. If the lesion is in the lumbosacral region, the automatic bladder will not develop although the bladder may regain some tone. Constipation from lack of rectal sensation and from loss of tone in the muscles of defecation may be controlled by small volume enemas, although occasional manual removal of faeces may also be needed. Trophic ulceration of the skin may be very troublesome in the early phase of paraplegia. Frequent gentle turning of the patient and careful nursing attention to

children are so relatively uncommon that it is obviously more difficult to maintain the same high index of suspicion.

The spinal cord may be compressed by direct invasion of tumour from without or by blood borne metastatic growths. According to Willis [8] direct invasion of the cord except as microscopic perivascular extension is unusual It probably occurred however in Case 4 where the spread was directly from the abdomen through the vertebral foramina Abdominal pain and pain in the back preceded the paraplegia and the pain was so severe that chemical destruction of the sensory nerve roots by phenol injections was seriously considered, but was anticipated by subsequent neoplastic destruction of those same roots with complete relief of pain and with the onset of complete anaesthesia. Direct spread of tumour probably also occurred in Case 5 Here the secondary tumour was in the vertebrae at the earlier stage when back pain and tenderness were present When the spinal canal became invaded events moved rapidly so that within a few days of developing weakness in one leg she had a complete paraplegia below the level of D5 and 6 with sensory loss and paralysis of the sphincters In Case 2 the histological diagnosis was never established. When he was first seen a posterior abdominal tumour was present and this could have spread to the cord by direct extension. Hypoglycaemia in Infantile Malnutrition

by E. KERPEL-FRONIUS and E. KAISER

Advance in knowledge of hypoglycaemia in infantile malnutrition was strikingly similar to that of hypoglycaemia in the semistarved adult and in the neonate. Many years passed after the first descriptions of hypoglycaemia before its capital clinical significance was recognized. This sceptical attitude which led to therapeutic nihilism may be explained by the following facts

1) Severe hypoglycaemia is not an obligatory feature of any of these clinical conditions, it occurs only in peculiar cases or at certain stages of the disease.

2) Hypoglycaemia, even if severe is by no means always symptomatic and the symptomatology presents some peculiarities.

3) Attention in these conditions was focused on other at first glance more important or more spectacular metabolic or clinical alterations

With regard to *hunger oedema in the adult* this attitude changed during World War II Although again most investigators devoted their interest to oedema and to protein metabolism, some French authors recognized that hypoglycaemia arising suddenly in extremely emaciated adults may be one of the ultimate causes of death [1].

Neonatal hypoglycaemia, first described by Van Creveld in 1929 [2], had also long been considered a harmless condition, even though Hartman & Jaudon [3] suggested already in 1937 that it may at times cause symptoms. The real clinical significance of this type of hypoglycaemia encountered in cases of intrauterine malnutrition, in infants of diabetic mothers, in prematures and in the respiratory distress syndrome is emerging only from systematic work done in recent years.

Hypoglycaemia in infantile malnutrition has the longest history for the first observations can be traced as far back as the classical period of German Paediatrics preceding World War I [4]. Although Jaso [5] in 1932 called attention to the prognostic significance of decreasing fasting blood sugar levels, the clinical significance of hypoglycaemia was not understood for many years Recent standard textbooks [6 7 8] do not even mention hypoglycaemia in their respective chapters on malnutrition, neither did Trowell [9] take any notice of it in his excellent book on kwashiorkor Abalil in 1950 [10] seems to be one of the first investigators to set the

the skin do much to limit it and the patient could be nursed on some type of alternating pressure mattress [1]. After paraplegia has been present for some weeks, there may be some return of tone in the muscles accompanied by flexor spasms. At this stage the condition of the skin does tend to improve and bed sores are more easily controlled.

Although vigorous efforts to control the primary disease should not be pursued beyond reason and humanity, it is essential to try and preserve the morale both of the child and his family by continued interest and attention to all details of his care and comfort.

Summary

1. Five cases of paraplegia due to secondary malignant disease in children are described.

2. There was one case of generalized lymphosarcoma; one case of acute leukaemia who had recurrent neurological complications, paraplegia developing terminally; one case of metastatic Wilm's tumour; one case of Ewing's sarcoma and one case in which the histological diagnosis was not confirmed, but was probably lymphosarcoma.

3. Tumours of the spinal cord and appendages are uncommon in children and are more often primary than secondary.

4. Spread to the spinal canal may be by direct extension from the abdomen or vertebrae or by blood borne metastases.

5. The management of paraplegia includes care of the bladder, the bowels and of the skin.

Submitted July 14, 1966
Accepted Sept. 1, 1966

We now come to the description of blood sugar levels found in the severe dry form of malnutrition in young infants. The degree of wasting of the body in these cases was extreme, and it is only inadequately described by percentile deviations of weight from average values for age or for length. Paediatricians working before World War I to whom of course, in this idyllic period in the history of mankind, the physical appearance of the victims of concentration camps was unknown and also unthinkable, stated that such a "physiologic misery" is unparalleled in any other age group in human pathology. It can be affirmed that a deficit of weight for length reaching 30 %, as found in these very young infants, certainly reflects a greater degree of wasting of the body than in older children or in adults.

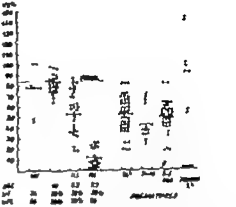

Fig. 1. *Fasting blood sugar levels in marasmic infants and in prematures. KW* = kwashiorkor; *M* = marasmus young children; *MI* = marasmic young infants ("atrophy" and "athrepsia"); *MIS* = young atrophic infants exhibiting symptomatic hypoglycaemia. Prematures 24, 24–48 hours, 3–6 days of age. *RD* preterm, respiratory distress cases within two hours of death. *WFA* deficit of weight for age; *WFL* deficit of weight for length.

Fasting blood sugar levels were in all these cases below the normal mean values. Twenty-one cases had one or more attacks of hypoglycaemia. During the attacks, the blood sugar ranged between 25 and 0 mg/100 ml with a mean value of 11 mg/100 ml. In this danger zone of blood sugar levels there is some overlap with asymptomatic cases: in 4 infants fasting values between 25 and 10 mg/100 ml had not been accompanied by symptoms. It is known that the same phenomenon, i.e. extremely low blood sugar levels with apparent well-being, may be also observed in newborn premature infants. For the sake of comparison Fig. 1 shows blood sugar levels in a number of our premature infants. Although some cases had values below 20 or even below 10 mg/100 ml, only one symptomatic case was observed in this series, an infant of a diabetic mother who had convulsions with a blood sugar level of zero, and who made an uneventful recovery following the intravenous administration of glucose solution. Glycaemia in prematures with respiratory distress raises a special problem. Our data show that in 40 % of all cases preterminal values were below 20 mg/100 ml, and that hyperglycaemia, which is exceptional in normal prematures, also occurred in a high percentage of the cases. This condition, when untreated, leads to mobilisation and preterminal depletion of carbohydrate stores.

Prognostic significance of hypoglycaemia. Low fasting blood sugar levels reflect the severity and the prognosis of malnutrition with higher fidelity than do changes in any other metabolic parameter.

All 10 cases of kwashiorkor and all malnourished gipsy children exhibiting no or only mild hypoglycaemia, survived.

facts in their true light He pointed out that of 20 cases of infantile marasmus 4 exhibited one or more attacks of hypoglycaemia while out of 35 cases of oedematous malnutrition (kwashiorkor) 23 showed hypoglycaemia which in 8 cases appeared to be the cause of death.

We became interested in this question in 1954 when we found that young marasmic infants exhibiting apnoeic spells had severe hypoglycaemia [11] These apnoeic spells announcing impending death from respiratory paralysis were described years ago by Finkelstein [12] and others who felt that they were preterminal signs of an irreversible disintegration of the respiratory center Our observations on eight cases exhibiting apnoeic spells accompanied by hypoglycaemia and promptly relieved by intravenous glucose solution, convinced us that this alarming picture is not irreversible but represents the clinical manifestation of spontaneous hypoglycaemia

This work is an analysis of the incidence the severity the clinical picture and the predisposing factors to hypoglycaemia occurring in the different types and stages of infantile malnutrition

Material and Methods

The material consists of (1) Ten cases of oedematous kwashiorkor like malnutrition occurring in this country exclusively in young gipsy children. (2) Twenty two marasmic gipsy children of about the same age exhibiting, however no oedema or hypoproteinaemia on admission. The aetiology of malnutrition in both these groups was the same, namely low intake of milk animal proteins and of calories, and poor hygienic conditions; (3) Fifty four young infants suffering from the severe, dry form of malnutrition known in classical paediatric terminology as severe atrophy athrepsia or decomposition. Twenty-one infants of the latter group exhibited one or more attacks of symptomatic hypoglycaemia. Malnutrition in these cases was due to inadequate feeding and congenital malformations. Specific coli infection in three quarters of all cases played, however the leading role. About one half of these cases were premature infants.

Venous blood drawn after 4–8 hours of fasting or during the hypoglycaemic attack was measured by the method of Somogyi and Nelson [13].

Results

Fasting blood sugar levels in their relation to clinical symptoms Fig 1 showing fasting blood sugar levels found in various types of infantile malnutrition, gives a general impression of the problem. Blood sugar levels in newborn prematures are presented in the figure for comparison.

In ten cases of kwashiorkor like oedematous malnutrition dangerously low blood sugar levels or clinical symptoms referable to hypoglycaemia were never encountered. The same is true of the next group of gipsy children of about the same age exhibiting no oedema on admission. It should be pointed out that the degree of malnutrition in these cases, although severe was not extreme Weight compared to that of normal infants of the same age showed a deficit of 34–35 %, it was smaller when weight was compared to that of normal children of the same length however This indicates that in these infants the percentile deviation from average weight for age is only in part due to emaciation and that stunted growth occurring invariably in malnutrition of long duration is also important

We now come to the description of blood sugar levels found in the severe, dry form of malnutrition in young infants. The degree of wasting of the body in these cases was extreme, and it is only inadequately described by percentile deviations of weight from average values for age or for length. Paediatricians working before World War I to whom, of course in this idyllic period in the history of mankind, the physical appearance of the victims of concentration camps was unknown and also unthinkable, stated that such a "physiologic misery" is unparalleled in any other age group in human pathology. It can be affirmed that a deficit of weight for length reaching 30 %, as found in these very young infants, certainly reflects a greater degree of wasting of the body than in older children or in adults.

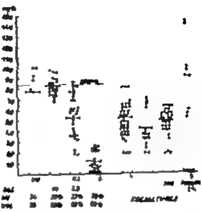

Fig. 1. *Fasting blood sugar levels in marasmic infants and in prematures.* KW = kwashiorkor; M = marasmic young children; M.I. = marasmic young infants ("atrophy" and "athrepsia"); M.I.S. = young atrophic infants exhibiting symptomatic hypoglycaemia. Prematures 24, 24–48 hours, 3–5 days of age. R.D. preterm. respiratory distress cases within two hours of death. W.F.A. = deficit of weight for age; W.F.L. = deficit of weight for length.

Fasting blood sugar levels were in all these cases below the normal mean values. Twenty-one cases had one or more attacks of hypoglycaemia. During the attacks, the blood sugar ranged between 25 and 0 mg/100 ml with a mean value of 11 mg/100 ml. In this "danger zone" of blood sugar levels there is some overlap with asymptomatic cases: in 4 infants fasting values between 25 and 10 mg/100 ml had not been accompanied by symptoms. It is known that the same phenomenon, i.e. extremely low blood sugar levels with apparent well-being, may be also observed in newborn premature infants. For the sake of comparison Fig. 1 shows blood sugar levels in a number of our premature infants. Although some cases had values below 20 or even below 10 mg/100 ml, only one symptomatic case was observed in this series, an infant of a diabetic mother who had convulsions with a blood sugar level of zero and who made an uneventful recovery following the intravenous administration of glucose solution. Glycaemia in prematures with respiratory distress raises a special problem. Our data show that in 40 % of all cases preterminal values were below 20 mg/100 ml, and that hyperglycaemia, which is exceptional in normal prematures, also occurred in a high percentage of the cases. This condition, when untreated, leads to mobilisation and preterminal depletion of carbohydrate stores.

Prognostic significance of hypoglycaemia. Low fasting blood sugar levels reflect the severity and the prognosis of malnutrition with higher fidelity than do changes in any other metabolic parameter.

TABLE 1 *Weight deficits blood sugar levels and mortality rates in infantile malnutrition.*

	Number of cases	% weight deficit for length	Blood sugar (mg/100 ml) Max	Mean	Min	Mortality rate ( )
Kwashiorkor	10	[illegible]	100	77	45	0
Dystrophy	[illegible]	23	[illegible]	82	6	0
Marasmic infants, blood sugar > 30 mg/100 ml	18	[illegible]	81	63	51	16.6
Marasmic infants, blood sugar < 50 mg/100 ml	13	[illegible]	30	34	14	[illegible]
Marasmic infants with sympt hypoglycaemia	1	29	[illegible]	11	0	[illegible]

Thus the presence or absence of oedema carries no reliable prognostic value In the young marasmic infants the death rate increased with decreasing fasting blood sugar levels and one half of the infants presenting symptomatic hypoglycaemia were ultimately lost Although the first attacks in those cases were relieved promptly by intravenous administration of glucose solution in 7 cases we were late in treating recurring attacks 4 infants died presumably from septicaemia due to coli infection.

Signs and symptoms The early signs and symptoms of hypoglycaemia seen in adults are absent or cannot be ascertained in malnourished infants. Table 2 summarizes the symptoms observed in our cases.

Deathly pallor or an ash grey colouring of the face was a constant sign In 10 out of the 21 first attacks the patients exhibited apnoeic spells mostly accompanied

TABLE 2 *Symptoms of hypoglycaemia in malnourished infants*

Convulsions	1

by slowing of the pulse rate. Convulsions appeared only exceptionally in severely malnourished young infants.

Conclusive proof that this condition resulted from hypoglycaemia was the effect of intravenous glucose solution. This was practically always a dramatic effect the colour and the general condition greatly improved while the respiratory and pulse rate increased (Fig 2)

Predisposing factors The tendency to spontaneous hypoglycaemia is revealed by the shape of the blood sugar curve during fasting Fig 3 shows the mean and the extreme values of five infants who a few days preceding this study exhibited attacks of spontaneous hypoglycaemia.

Blood sugar levels studied at hourly intervals in normal or not extremely malnourished infants remained unchanged for six hours following the last meal In many cases of extreme malnutrition blood sugar decreased progressively the slope of the fasting curve being steepest 3–4 hours following the last meal

The degree of hypoglycaemia as well as the appearance of clinical symptoms were roughly correlated directly to the degree of malnutrition as expressed by the deficit of weight for length (Fig 4)

Fig. 2

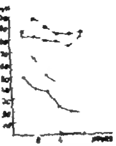

Fig. 3

Fig. 4. *Fasting blood sugar levels in infants as function of weight deficit for length.* Closed circles represent symptomatic cases.

Attacks of spontaneous hypoglycaemia sometimes appeared in the group with weight deficits between 25–40%. In a great number of infants with this degree of malnutrition fasting blood sugar did, however, not fall to dangerous levels.

Analysing the factors predisposing to hypoglycaemia in the neonate, Cornblath [14] drew attention to the high brain/liver ratio in this age group. He pointed out that the relatively large brain is the chief user of blood glucose, the relatively small liver being the endogenous source of blood glucose. Organ proportions in malnutrition change in the same unfavourable direction, as shown in thirteen of our extremely malnourished young infants (Fig. 5).

Liver weight is only [illegible]0% of that in controls of the same age, while the brain appears to be almost unaffected by malnutrition. This results in a brain/liver ratio of about 5 as contrasted to that of 3.6 found in controls. The same change takes place in the malnourished adult. We calculated from available organ weights [15] the brain/liver ratio of victims of the Warsaw Ghetto during World War II, it was more than double that of the normal adult. While increased brain/liver ratio certainly appears to predispose to hypoglycaemia, its effect is felt only in cases with undermined blood sugar regulation. This conclusion is warranted by two facts: (1) low blood sugar levels and symptomatic hypoglycaemia occur only in some, but not all extremely emaciated subjects and (2) stabilization of glycaemia in individuals with symptomatic hypoglycaemia may occur before the beginning of catch-up growth, therefore, without change in the brain/liver ratio (Fig. 6).

A possible factor predisposing to or provoking hypoglycaemic attacks may be *intestinal malabsorption of carbohydrates*. In an earlier study on 02 cases of malnutrition, severe impairment of lactose splitting was found in about one quarter of the cases, while malabsorption of sucrose or monosaccharides was rare and seldom severe [16]. Since our oedematous protein-calorie malnutrition cases, though poor absorbers of lactose, did not exhibit hypoglycaemia, we may surmise that carbohydrate malabsorption is not a decisive

TABLE 1 *Weight deficits blood sugar levels and mortality rates in infantile malnutrition*

cotrophine or adrenal steroids. A treatment of 10 days increased and stabilized the fasting blood sugar levels in most of our symptomatic cases. In three cases, however this effect was only transitory and recurrences of symptomatic hypoglycaemia required renewal of treatment.

Discussion

The literature on the incidence the clinical significance and pathogenesis of hypoglycaemia in malnutrition contains many contradictions. In kwashiorkor some authors found low [10 17] and others [18, 19] normal or nearly normal blood sugar levels. *Attempts to elucidate the* origin of hypoglycaemia by studying the response to epinephrine and insulin, as well as glucose tolerance tests *yielded* contradictory results. Liver glycogen has been studied but in few cases [10 20] and only exceptionally in cases exhibiting hypoglycaemia *(10)*

The explanation of these contradictions may be found in the following facts: the *breakdown of blood sugar regulation* is by no means a metabolic change occurring in all cases of malnutrition The most important predisposing factor is a severe degree of wasting of the body This, however is not necessarily reflected by the low body weight of the patient as compared to that of *normal infants of the* same age, i e by the index generally used to express the severity of malnutrition. We have called *attention to this fact in* an earlier investigation [21], *indicating* that owing to the arrest of growth, many of the low weight for age infants are small rather than extremely thin. Fig 4 shows, however that the tendency to hypoglycaemia appeared only in infants in whom the weight deficit for length exceeded 20-25% of their initial weight. Such young infants lost practically all their subcutaneous fat and clinically they looked extremely marasmic. As to kwashiorkor we feel that the practice to consider the appearance of oedema and the low weight for age index as criteria of *the severity of protein-calorie* malnutrition explains contradictory reports about the incidence and the severity of hypoglycaemia. Oedema, although a spectacular symptom, does not indicate that malnutrition is in its severest phase Experience shows that protein-calorie malnutrition *which is severe enough to* cause conspicuous changes in certain parameters, namely hypoproteinaemia, oedema decreased *activity* of pancreatic enzymes and of *intestinal* lactose splitting ability [21] is not by necessity associated with simultaneous breakdown of blood sugar *regulation. It should be pointed out* that although our cases of kwashiorkor exhibited all the alterations enumerated above, they were neither extremely emaciated, nor hypoglycaemic. Thus, we assume that the hypoglycaemic cases of kwashiorkor described by some of the authors who studied this *problem, must* have been not only oedematous, but also extremely wasted. This assumption is in *keeping with the* experience *with fatal* cases of hypoglycaemia in malnourished adults during World War II Wasting in *all these cases* was extreme and comparable to that seen in our young atrophic and hypoglycaemic infants.

While an extreme degree of emaciation and consequent changes *in organ* proportions should be considered as important

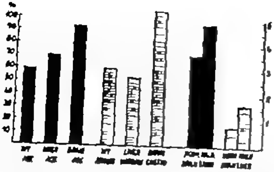

Fig 5 Brain/liver weight and ratio in hypoglycaemic marasmic infants and in semi-starved adults 100% = normal weights for age Black columns = infants. The two pairs of columns on the right show the brain/liver ratios in normal and in malnourished individuals respectively

factor in the origin of hypoglycaemia Evidence in favour of this point is added by observations made in three cases of young coli infected marasmic infants in whom lactose and sucrose absorption following the oral administration of 2 5 g sugar per kg body weight was studied during severe hypoglycaemia

Increments in blood sugar in all these cases were satisfactory and hypoglycaemia was relieved both by lactose and by sucrose loading Defective splitting or absorption of carbohydrates, may be a

factors predisposing to low blood sugar levels the dramatic rapidity with which hypoglycaemia and an alarming clinical picture sets in suggests low glycogen reserves and a slow rate of gluconeogenesis. The sudden breakdown of blood sugar regulation follows intestinal infections and stresses always appearing during the acceleration of the wasting process. On the *other hand, this* severe disturbance is to a certain extent self limited which disappears following the elimination of infection and the introduction of a proper diet even before catch up growth sets in. It is only to be expected that liver glycogen *content epinephrine* insulin and glucose tolerance tests will yield variable results depending upon the phase of the disease during which these studies were undertaken [18 19 22 23] In brief the study of blood sugar regulation in malnutrition should be approached as a dynamic not *as a static problem* Unequivocal results can only be expected when carbohydrate metabolism is studied comparatively in the hypoglycaemic and in the non hypoglycaemic phase of malnutrition. Such studies are now in progress.

Summary

The incidence the clinical significance *and the* factors predisposing to hypoglycaemia were studied in 84 malnourished *infants.* Predisposing factors were young age intestinal infections extreme wasting of the body the deficit in weight exceeding 25 % as compared to normal infants of the same length and even brief periods of fasting Older oedematous infants, if not extremely marasmic were not hypoglyc*aemic.* Malabsorption of carbohydrate does not play a leading role in eliciting hypoglycaemia since severe hypoglycaemia was also observed in cases in whom the ability to split disaccharides was preserved.

The prominent clinical symptoms at blood sugar levels between 25 and 0 mg/100 ml were pallor and apnoeic spells, while convulsions were exceptional. There was a prompt response to intravenous glucose and recurring attacks were generally prevented by frequent feeding and by the administration of corticoids. Some cases *exhibiting* very low blood sugar levels remained asymptomatic Fasting blood sugar levels were found to be of great prognostic significance

Acta Pædiatrica Scandinavica Supplement 172 1967

From the Pediatric Clinic of Athens University

Clinical Considerations, EEG and EMG Studies, in Subacute Sclerosing Leucoencephalitis

by V KYRIAKIDOU

The clinical picture of subacute sclerosing leucoencephalitis [6 7] (SSLE) which includes intellectual deterioration, involuntary repetitive movements and a subacute course is very characteristic The demonstration of rythmic complex discharges in the electroencephalogram (EEG) [2 3 8, 10 11 12] coinciding with the involuntary movements provided a valuable adjunct to the premortem diagnosis of the disease The results of several studies [1 15] have left no doubt that the Van Bogaert [14] SSLE the Dawson inclusion body encephalitis [4 5 13] and the Pette-Döring [9] panencephalitis are one and the same condition.

In this paper clinical observations the EEG and electromyographic (EMG) phenomena are reported from 8 cases seen at the Pediatric Clinic of Athens University during the last 3 years.

Methods

In all 8 patients EEG tracings were recorded repeatedly during the course of the disease. EMG studies with surface electrodes were made in two patients. Both EEG and EMG recordings were performed on an 8 channel Alvar apparatus. 21 electrodes were used contact being made through a saline jelly Bipolar and average reference recordings were used. The paper speed varied from 1.5 cm to 3 cm/sec The constant time was in the order of 0.3 sec for the EEG and 0.1 for the EMG

Results

Clinical observations

These are summarized in Table 1 In the first stage of the insidious onset of SSLE the clinical picture consisted of early and progressive intellectual deterioration and severe involvement of all psychic functions diminution of scholastic ability short attention span, apathy as well as memory disturbances. These symptoms sometimes noted only in retrospect were accompanied or followed by episodic staggering clumsiness drop attacks or convulsive like episodes.

Five patients (cases 1 2 3 6 7) had gait difficulties caused by frequent fal[ls] Head drop attacks were noticed in [.] patients (cases 1 2 4 5 6 8) with rev[ul]sion of the eyes in one (case 2) The attacks were mistaken for akinetic [sei]zures. Grand mal fits occurred in o[ne] patient (case 5) Focal myoclonic jerki[ng] in the form of epilepsia partialis contin[ua] developed in two patients (cases 3 and [.]

Later variable rythmic involunta[ry] movements appeared in all patients. The

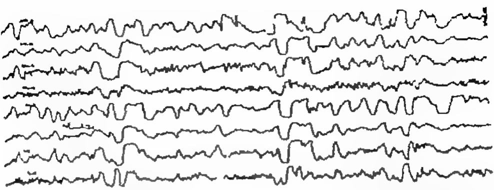

Fig. 2a. Case 7: Male, 6 years. EEG on admission, in waking state. On relatively slow record, with some preservation of rythms up to 7 c/s, periodic discharges, 2 per second, are represented, consisting of high potential very slow irregular waves, preceded by a diphasic, slow sharp wave. (Paper speed 3 cm/s.)

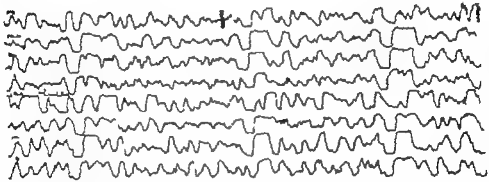

Fig. 2b. Same patient, 4 days later. The background activity is slower. The discharges are clear and large with nearly the same periodicity and shape.

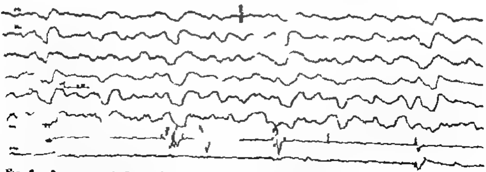

Fig. 2c. Same patient, 3 months later. Semicoma, continuous jerking movements on the left, tetraplegia, rythmic myoclonic seizures, dementia. EEG: On very slow background only the rythmic EEG complexes are distinguishable. EMG of the left and the right biceps. EMG discharges on the left correspond to the beginning of the EEG complexes.

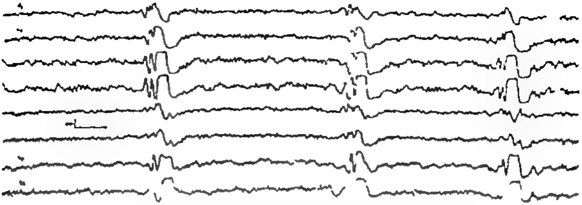

Fig 1 Case 5: Male 11 years. EEG on admission, in waking state. Rythmic discharges, 9 per second on a relatively organized backround activity with slight asymmetry and a more clearly defined alpha rythm at right. Note the similarity of complexes, consisting of burst of high voltage sharp waves followed by a slow wave (Paper speed 1.5 cm/s.)

were classified as follows (a) stereotyped repetitive jerking movements of isolated muscles groups. (b) widespread, spontaneous rythmic myoclonic-like seizures, repeated fairly constantly at 5 10 or 20 seconds and coinciding with the EEG rythmic complexes These seizures could be provoked by stimulation and were abolished in deep sleep or narcosis, during which the EEG complexes persisted (c) Fine continuous tremor limited to one or more hypertonic limbs.

The ocular fundi were normal in all but 1 patient who showed pigmentary macular degeneration.

In a later stage all patients deteriorated to almost complete dementia Neurologic examination at this time revealed semi coma or coma with hypertonia and spastic quadriplegia sometimes with focal neurological signs. Seven patients died within 2–8 months following hospitalizations

EEG and EMG studies

In each case rythmic complexes were seen at intervals of 5 to 20 seconds or 4 to 12 times a minute they invariably coincided with the stereotyped involuntary movements (Figs. 1 and 2a b c) In one patient EEG discharges disappeared temporarily while jerks persisted. There was some individual variation in the pattern of the EEG discharges; however in each patient the complexes were always the same The usual form of the rythmic complexes consisted of bursts of high voltage slow waves preceded by one two or more rapid or slow sharp mono- or diphasic waves on a more or less disorganized background A period of relative silence sometimes followed the complex. As the disease progressed the basic tracing became slower and usually showed complete disorganization with very slow irregular background activity Rythmic discharges persisted but became less evident so that they sometimes became hardly distinguishable from the generalized irregular slow waves. In deep sleep spontaneous jerking ceased but the rythmic complexes not only persisted, but were more clearly defined The same activation

of the periodic discharges appeared to occur during photic stimulation.

The onset of the EMG discharges coincided with the beginning of the EEG complex (Fig 2c)

Comments

Since autopsy was refused in all cases, pathological confirmation of the diagnosis is lacking. This is why only typical cases have been included in this report. The present clinical and EEG observations indicate that diagnosis of SSLE is not difficult. Early mental deterioration and the occurrence of repetitive involuntary movements, coinciding with the rythmic EEG complexes, are the main features of this disease. The strongly left-zonal or paretic colloidal gold curve (Lange) in the cerebrospinal fluid is a valuable laboratory test. Important diagnostic criteria are also provided by the age and sex of the patient, the subacute course and the fatal outcome.

The assumption that involuntary movements of SSLE are different from myoclonic seizures is open to question. Some authors believe [7, 8] that the myoclonic spell in SSLE begins as abruptly as the true myoclonic jerk, but that unlike the latter it is longer and ceases gradually.

The EEG study revealed rythmic complexes in repeated recordings in all but two of our patients. In one case (case 1) periodic components disappeared temporarily while jerks persisted. In the second patient the first EEG taken 2 months after the onset of symptoms, was normal. At this time the child presented akinetic spells with memory and behaviour disturbances. Two months later he had EEG changes which were characteristic of SSLE. The constant relationship between the repetitive movements and the periodic EEG discharges was invariably seen in our patients. During sleep or photic stimulation some activation of the periodic events was noted.

Summary

Clinical considerations, as well as EEG and EMG studies from 8 patients, 7 males and one female 5 to 11 years old, with SSLE are reported.

Mental deterioration, involuntary rythmic movements coinciding with periodic EEG complexes, were constant findings. In all cases the EEG showed periodic discharges at intervals of 5 to 20 seconds, on a more or less disorganized background activity. The EMG study revealed that the action potentials of the involuntary movements occurred at about the beginning of the periodic EEG changes.

In deep sleep spontaneous jerking ceased while the EEG complexes persisted.

Some activation of the rythmic discharges in the EEG appeared to occur during sleep and photic stimulation.

neat un liquide opalescent. Elles siègent sur les piliers antérieurs du voile du palais, sur la luette et, plus rarement sur les amygdales et la paroi postérieure du pharynx, très exceptionnellement sur la face interne des joues et la langue. Elles sont bilatérales, irrégulièrement réparties de part et d utre de la ligne médiane, isolées et non groupées, jamais confluentes; elles peuvent ne siéger que d'un côté. Elles sont en petit nombre 5 à 6, une quinzaine u plus.

L évolution de ces lésions est très rapide en quelques heures, 48 heures au plus, elles passent de la phase enanthémateuse à la phase vésiculaire, des vésicules à liquide clair aux vésicules à liquide louche ou pustules, et à la phase ulcéreuse. Leur rupture laisse place à des exulcérations ou ulcérations petites, arrondies, à fond gri sâtre.

L engorgement des ganglions satellites (sous-angulo-maxillaires) est nul ou seulement modéré.

L'hémogramme est normal, sauf en cas d'infections bactériennes surajoutées.

A côté des formes typiques on peut observer des formes typiques

— formes seulement érythémateuses, sans vésicules ni ulcérations.
— formes fébriles pures, réduites à des signes généraux.
— formes accompagnées d éruptions cutanées.
— formes compliquées de troubles digestifs vec diarrhée, ou de parotidite [3], ou d accidents laryngés simulant le croup ou encore d'acci dents méningo-encéphalitiques.

On tend à admettre la possibilité de formes cliniquement asymptomatiques (porteurs sains de virus) ne donnant lieu qu à des modifications sérologiques (ascension des anticorps neutralisants).

Le diagnostic clinique dans les formes typiques, est facile. On éliminera sans peine le muguet, les angines érythémato-*pultacées*, l énanthème de la varicelle. Marfan a bien montré les caractères qui séparent ce qu il appelait l « angine pustuleuse » de l angine et de la stomatite herpétique, — ainsi que ceux qui la distinguent de ce que les classiques décrivent sous le nom d angine aphteuse, expression qui couvre, chez l'homme un syndrome dont l étiologie est encore mystérieuse.

Le diagnostic virologique est basé sur l'isolement du virus. Les enquêtes systématiques effectuées à l occasion de certaines épidémies, ont d une manière quasi constante, permit l'isolement de virus Coxsackie du Groupe A. Le type le plus fréquemment rencontré a été le type 4, mais on a observé également les types 1 2, 3 5, 6 7 8, 9 10, 16 et 22. L'isolement se fait facilement dans les selles ou la salive, plus difficilement à partir de prélèvement pharyngés, car dans la gorge le virus ne persiste guère plus de trois jours.

L ascension des anticorps déviant le complément ou des anticorps neutralisants tteint un taux élevé dans le mois qui suit l'infection, permettant ainsi un diagnostic rétrospectif. Ce taux élevé persiste plusieurs semaines, voire 3 à 4 mois.

Les recherches virologiques les plus récentes ont compliqué le problème étiologique. L ascension simultanée des anticorps antipoliomyélitiques n est pas ex ceptionnelle mais sans doute s agit-il ici d une simple coïncidence. Par contre dans certaines épidémies d'herpangine, on a invoqué la responsabilité des virus Cox

L herpangine ou angine de Marfan-Zahorsky

par MARCEL LELONG

Le terme d « herpangine » a été créé aux États-Unis en 1924 par J Zahorsky [6] pour isoler une entité clinique distincte de l angine herpétique et à laquelle il rattachait des faits qu il avait publiés en 1920 mais qu à l époque il avait reliés à l herpès. En février de la même année Marfan [5], à l aide de 9 cas personnels, avait décrit sous le nom d « angine pustuleuse » un type d angine qu il séparait nettement de l angine herpétique d une part et de l angine aphteuse d autre part. A ces deux auteurs nous devons donc l individualisation clinique du syndrome. Des deux termes proposés aussi mal choisis l un que l autre c est celui d'herpangine qui a été retenu par l usage international malgré la confusion regrettable qu il laisse persister avec l herpès Aussi serait-il mieux de parler d angine de Marfan–Zahorsky

C'est à R J Huebner *et coll.* [4] que revint le mérite d avoir par des études épidémiologiques et virologiques poursuivies méthodiquement dès 1949 démontré la responsabilité des virus Coxackie A. Par la suite leurs conclusions ont été vérifiées dans de nombreux pays d Amérique, d Europe et d Asie. En France J Gerbeaux *et coll.* [2] ont présenté en 1960 une étude clinique et virologique d une épidémie hospitalière avec isolement d'un virus Coxackie A4

L'herpangine est une maladie saisonnière et surtout une maladie d été elle s observe le plus souvent de Juin à Octobre Elle frappe avec prédilection les enfants de moins de trois ans. Il en existe des cas sporadiques, mais tous les auteurs soulignent son caractère épidémique. La plupart des épidémies concernent des collectivités : hôpitaux crèches, pouponnières, ou familles. La durée de l incubation est assez courte 3 à 5 jours.

Dans sa forme typique la maladie débute brusquement par une montée fébrile à 38° 5–39 ou même 39 –40°C. Cette fièvre persiste deux ou trois jours. Elle peut s accompagner de céphalée, de vomissements de douleurs thoraciques ou abdominales, de myalgies, et même de convulsions.

Dans les deux tiers des cas, la dysphagie attire l attention vers la gorge A l examen, celle-ci montre des lésions caractéristiques. Sur un fond d érythème pharyngé diffus, plus intense sur les bords libres du voile du palais et sur la luette se voient des vésicules arrondies hémisphériques ou même coniques, de 1 à 2 mm de diamètre. Entourées d une petite auréole rouge elles sont de couleur blanc grisâtre et contien

Body Temperature of the Newborn Infant in Relation to Placental Transfusion[1]

by WILLIAM OH,[2] and JOHN LIND

When clamping of the umbilical cord is delayed at birth, the newborn infant receives a sizable amount of placental blood transfusion [9, 26]. Measurement of blood volume in these *infants* during the first 30 minutes after birth revealed that this placental blood transfer could amount to at least 33% of the infant's original blood *volume [21, 27]*. The blood volume difference resulting from early or late cord clamping has been shown to significantly influence the normal hemodynamic changes immediately after birth [4, 5, 18, 19, 20].

This communication deals with the body and skin temperature changes of infants with early or late cord clamping during the first 5 days of life.

Material and Methods

The subjects of this study were thirty-six newborn *infants* delivered vaginally at the Sodra Barnbordshuset (Southern Maternity Hospital) Stockholm, Sweden, after 38 to 42 weeks *of gestation. The course of* the pregnancies, labors and deliveries were uncomplicated. The average duration of labor was 10 hours and 36 minutes (range 5 to 23 hours); 15 of the mothers received intermittent inhalation of short duration of nitrous oxide ½ to 3 hours before delivery. There were 17 male and 19 female infants with an average birth weight of 3,560 g (range 2,900 to 4,520 g). All infants had an Apgar score [1] of 8 to 10 at 5 minutes of age. None of the infants developed any illness or complication during the period of observation.

In one study skin temperatures of 30 infants were serially followed from 5 minutes to 5 days of life. These *infants* were divided into two groups according to the time their umbilical cords were clamped at birth (the delivery of the infant's buttocks was considered as the time of birth).

Group I. Late clamped group (*16 infants*). Cords were clamped after the umbilical arterial pulsation had stopped. Average time of clamping was 3 minutes 48 seconds after birth (range 2 minutes 30 seconds to 5 minutes).

Group II. Early clamped *group* (14 infants). Cords were clamped immediately after birth. Average time of cord clamping was 9.0 seconds after birth (range 3 to 20 seconds). No attempt *was made to milk* the cords in the late clamped group. The timing *of* cord clamping was not related *to the* onset of respiration. The delivery bed of the infants was about 10 cm below the plane of the mother's introitus.

of life are summarized in Table 3 and graphically presented in Figs. 2 to 5.

An initial drop in peripheral temperatures (heel and palm) occurred during the first 30 minutes of life. Thereafter the temperatures in these skin areas became stabilized but remained at low levels during the first four hours, when infants were kept at a room temperature of 24 to 26 with adequate clothing. At 24 hours of age all infants maintained a steady skin temperature averaging from 30 to 31.6 C. The room temperature of the nursery was also maintained at 24 to 26°C.

Soon after birth and during the first 4 hours of life the early clamped infants had a significantly lower skin temperature in the heel and palm than the late clamped infants (Table 3).

Five to ten minutes after birth, the earlobe skin temperatures were already noted to be lower than the intrauterine

During the first 4 hours of age the infants were kept in an observation room where the temperature varied between 24 and 26°C The infants were placed in bassinets during the first hour and were covered with one cotton sheet and one woolen blanket Between one and 2 hours, the infants were briefly washed with warm water weighed and measured for their head circumference and body length and were then clothed with one cotton dress, a cotton diaper and again covered by a cotton sheet and a woolen blanket. These routine procedures usually lasted for 15 to 20 minutes. The extremities of the infants were enclosed in the sheet and blanket.

At 5 to 10, 15, 45 and 60 minutes of age the rectal temperatures were taken using a conventional thermometer inserted 3 cm deep into the rectum, skin temperatures on the center of both heels, epigastrium, the center of both palms and the anterior surface of both earlobes were taken with an electrical thermometer type TE 3 (Ellab Instrument Copenhagen) using the type H 1 skin applicator The response time of this electrode was 1 to 3 seconds. During each measurement the skin applicator was applied on the areas to be measured for 3 to 5 seconds and the readings recorded when it became stable An average of two readings was obtained on each side in the case of heels, palms and earlobes. In the case of earlobes the reading of the side on which the infants head was lying was usually higher than that of the exposed side; but during the first 4 hours of life the difference of paired readings did not exceed 0.5°C and comparison of the readings of the exposed sides alone to the average readings of both earlobes revealed no significant difference The rectal and skin temperature readings were repeated at 2, 4, 24, 48, 72, 96 and 120 hours of age Additional rectal temperature measurements were made at 5 and 6 hours of age. The measurements during the first hour of age were made at variable times of the day depending on the time of delivery while the daily readings were made between morning feeding schedules (between 9 a.m. and 1 p.m.)

No other procedures were done on these infants except for a scalp venipuncture at ½ hour of age to determine venous hematocrits. The hematocrits were measured by the microtechnique described by Guest and Siler [11]

In a separate experiment, the skin temperature of 6 infants whose cords were clamped late was measured from birth through 15 minutes of age. When "crowning began, the temperature of the scalp was measured when it appeared in the vulva during each uterine contraction. When the infant was delivered, the heels and palms were wiped dry with gauze and skin temperatures were measured at 0, 15, 30, 45, 60 seconds and every minute thereafter until the 15th minute after birth.

Results

There was no significant difference in the sex distribution birth weight and duration of labor between early and late clamped infants. At ½ hour of age, the early clamped infants had significantly lower hematocrit values than the late clamped infants (Table 1) This is ascribed to a higher blood volume in the latter group of infants, as had been demonstrated previously [27]

In six infants whose skin temperatures were continuously recorded from birth through 15 minutes of life (Fig 1 Table *) the heel and palmar skin temperatures averaged 35 4 C at birth and this was followed by a steep drop of 6°C within the first 15 minutes of extra uterine life

The scalp temperature averaged 34 8°C a few minutes before birth it fell by 2.6°C at 5 minutes but rose by 1 C during the next 10 minutes.

The serially measured skin temperatures of 16 late and 14 early clamped infants from 5 to 10 minutes through the 5th day

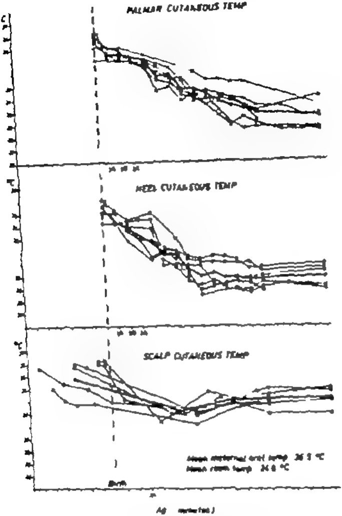

Fig. 1 Palmar heel and scalp cutaneous temperature changes in 6 newborn infants from birth through 15 minutes of age. Each line connects consecutive readings of each infant, and the heavy lines represent the mean values.

temperature environment. The early clamped infants had a mean temperature of 31.5°C while the late clamped infants, of 32°C. *Unlike the heel and palm tempera*tures which revealed an initial drop the earlobe temperatures showed a gradual rise during the first 4 hours of life. Scalp temperatures were not studied beyond 15 minutes of age however it is quite likely that the skin temperature changes of the scalp parallel those of the earlobes. *Unlike the heel* and palmar areas, only a slight difference in earlobe temperatures was observed between the early and late clamped infants: *the early clamped infants* had lower earlobe temperatures than the

late clamped infants at 15 minutes 4 and 24 hours of age.

The rectal and epigastric temperature curves of the early and of the late clamped infants are shown in Fig 5 The rectal temperatures at birth averaged 36 7°C in the early clamped infants and 36.5°C in the late clamped infants, and both

groups showed an initial fall during the first t o hours, followed by a gradual rise in the third hour and reaching stable levels at the 4th hour of life. The skin temperature on the epigastrium of the early clamped infants immediately after birth averaged 33.6°C while that of the late clamped infants 33.3°C. A gradual rise thereafter ensued, the temperatures reaching 35.7°C and 35.8°C at 4 hours of age in early and late clamped infants, respectively with no significant difference between the two groups (Fig 5).

Comments

The peripheral skin temperatures of newborn infants drops precipitously immediately after birth, probably as a result of sudden exposure of the neonate to a cold environment, since these infants are transferred within seconds from an intra uterine temperature environment to the delivery room with a temperature of 4°C. The effect of this abrupt postnatal change in thermal environment (during the process of delivery) upon the initial circulatory and respiratory changes following birth was not the object of this investigation However it seems pertinent to mention that this environmental change may play an *important role in the initiation of* the first breath.

It is of interest that the skin temperature of the earlobes did not exhibit the fall noted in the skin of the palms and heels during the first hours of life. This is perhaps related to the anatomy of the cutaneous blood vessels of the earlobes which differ from those elsewhere in the body in that arterio-venous shunting is abundant as shown in animal experiments [12]. This anatomical peculiarity could also explain the smaller difference in earlobe cutaneous temperature between early and late clamped infants which may be due to greater individual variations.

The rectal temperature changes observed in this study during the first 5 days of life are in agreement with the results of other workers [7 15, 25] No significant difference was found in epigastric and rectal temperatures between the early and late clamped infants during the first 5 days of life. *The low rectal temperatures during the first few hours of life have been attributed by Bruck [3] to Immaturity of the* infant s thermoregulatory mechanism" *Recent works have shown that chemical* thermogenesis in the newborn infant depends largely on noradrenaline [13 16 24]. When the newborn infant is exposed to a cold environment, it promptly responds with increased heat production, by augmenting brown fat metabolism, and with reduction of heat loss by peripheral vasoconstriction, both mediated by nor adrenaline The persistently low rectal temperatures during the first 4 hours of life suggest that for some as yet unknown reason chemothermogenesis was not adequately achieved

In this study the factors which might *affect the infants* skin temperature such as the amount of clothing, room tempera ture [23], *body weight [8] and the clinical* condition of the infants [14] were relatively similar in both groups *of infants. The* significantly lower skin temperatures of early clamped infants, particularly in the palms and heels, could be explained by a comparatively smaller skin blood flow in these subjects This, in turn, may be due to their smaller blood volume and greater

cutaneous vasoconstriction. It has been suggested that the newborn infants possess an intact vasomotor reflex pathway as early as their first day of life [17 22]. Although cutaneous temperature does not always reflect skin blood flow variation [6 10] it is generally agreed that within certain limits, the two are positively correlated [2]. Variations in regional skin blood flow have not been investigated obviously because of technical difficulties, although it seems logical to assume that they exist particularly in areas exposed to different thermal environments. Varying degrees of regional vasoconstriction may be an important factor in this situation. This may perhaps explain the higher skin temperatures in the unexposed epigastric area as compared to those of the hands and feet, and the similarity of the epigastric skin temperatures of the EC and LC subjects in this study.

Summary

Temperatures of the rectum skin areas of the heels, palms, earlobes and epigastrium were serially measured in 36 normal full term newborn infants from birth through the 5th day of life. The umbilical cords of 14 infants were clamped immediately after birth while in 22 infants the cords were tied after arterial pulsation had stopped. At birth the mean skin temperatures of heels and palms dropped precipitously from 35.4 C to 29.8°C during the first 10 minutes of life. The heel and palm temperatures showed a further decline during the first 4 hours of age while the earlobe and epigastrium temperatures gradually increased at the same time.

The early clamped infants had a significantly lower skin temperature at the palms, heels and to a lesser extent at the earlobes. This is considered as indirect evidence of lower peripheral skin blood flow in this group of infants. No difference was observed in the cutaneous epigastric and rectal temperatures between the two groups.

if not all appears to be of fetal origin [41, 45].

Until only a few years ago hypo- or agammaglobulinemia could be demonstrated by paper electrophoresis only when the total gamma-globulin was markedly reduced or absent. To-day by immunoelectrophoresis and other refined methods, it is possible to identify and to measure precisely the various Ig fractions and to correlate their absence with specific immunologic defects.

It is well established that patients with severe hypogammaglobulinemia are highly susceptible to bacterial infection and that they fare very poorly when they are affected by bacterial infection, their immunological behaviour to viruses is normal, although they are uncapable of forming antiviral antibodies. These patients are not susceptible to reinfection upon exposure to viruses with which they had been previously infected. Tuberculosis runs a normal course in these individuals [19] and the addition of phytohemagglutinin (PHA) to cultures of their peripheral blood produces a normal lymphocytic response. However, cultured lymphocytes do not stain with fluorescent antigamma globulin, nor do they incorporate radioactive aminoacids into gamma-globulin [22]. All these indicate that individuals with agammaglobulinemia, although lacking the ability to develop humoral resistance, are capable of developing cellular resistance.

In 1950 Glanzman and Riniker described two babies with the clinical and pathological findings of a syndrome which they

Dangers of Immunization in Immunologically Incompetent Individuals

by N MATSANIOTIS

For a long time immunity has been conveniently divided into two components, humoral and cellular The first is represented by the immunoglobulins, the products of antibody forming cells the second is strictly associated with the lymphocyte and is mainly expressed as delayed hypersensitivity This distinguishing of immunity with increasing knowledge becomes more and more vague and in a few years it may seem obsolete However for purposes of better understanding this distinction cannot be discarded for the time being

Since Bruton s first description of congenital agammaglobulinemia some 15 years ago much progress has been made towards a better understanding of the multifold nature of the human immune response

The tremendous evolution of the basic sciences provided the means to investigate the human immune response in detail It was shown for example that each specific gamma globulin antibody differs in structure from all other gamma-globulins having a different antibody specificity in other words that a specific antibody activity depends upon the chemical structure of the immunoglobulin molecule [10 11]

The nomenclature of human immunoglobulins adopted in 1964 at the meeting of WHO in Geneva [8] is shown in Table 1 It is wise to use these terms in order to avoid confusion in a field which is progressing so rapidly

In Table 2 the main biological and biophysical properties of the immunoglobulins (Igs) have been summarized.

Recent work by van Furth and his colleagues [44] indicates that the fetus and the newborn, both premature and full term, are to some degree capable of forming IgG and IgM. Synthesis of significant amounts of IgG begins at one month of age reaching adult levels at the age of two years. Following appropriate antigenic stimulation IgG appears in the serum right after IgM.

IgA is mainly produced by plasma cells lying in large numbers in the subepithelial layer of mucous membranes. They are secreted actively by the acinar and the epithelial cells of the salivary glands, as well as by the glands of the respiratory and gastrointestinal tracts Serum IgA probably represents transport IgA These Igs are not produced by the fetus nor do they cross the placenta

In the newborn the serum IgM level is only 1/10th of the adult level [44] Most

with thymic alymphoplasia but normal Ig levels. There is considerable evidence that the thymus not only supplies peripheral lymphoid organs with immunologically competent cells, but also elaborates through its reticular epithelial cells a factor(s) necessary for the normal immunologic development of exothymic lymphocytes [24]. The presence of a dysplastic thymus implies a defect in a very early stage of the evolution of the immune mechanism. This may involve, to a different degree both the development of the thymus, and hence the immunologic competence of the circulating lymphocyte, and the biochemical maturation of the plasma cell which may elaborate normal amounts of immunologically inefficient gamma-globulin. This, of course, is merely a hypothesis which must await proof, but it appears to fit very well with the expression of immunologic deficiency in these patients.

The various immunologic deficiencies have been summarized in table 3. Patients with the pure Bruton type of agammaglobulinemia do not appear to be at risk, if vaccinated with vaccines containing toxoid, killed bacteria or even living attenuated bacteria [17]. Since they are unable to produce detectable antibody their only danger following diphtheria or tetanus toxoid vaccination, for example, lies with the fact that they have acquired no immunity at all, in spite of their vaccination.

Most if not all BCG vaccinated agammaglobulinemic children develop tuberculin hypersensitivity and acquired resistance to tuberculosis [19]. Furthermore, with few exceptions these children have been vaccinated against smallpox with no untoward reaction. Both primary takes and accelerated reactions have been observed and, although antibodies do not appear in the serum following vaccination, these chil-

termed essential lymphocytophthisis [18] Many more cases have been described since under the terms of congenital agammaglobulinemia with lymphopenia thymic alymphoplasia or alymphocytosis, familial lymphopenia or the Swiss type of agammaglobulinemia. The salient features of this syndrome which constitutes the second major class of immunologic incompetence are (a) a downhill clinical course leading to death within the first two years of life, (b) agammaglobulinemia (c) a lymphocyte count which is usually though not invariably low (d) inability to develop delayed hypersensitivity and/or to reject homografts and (e) aplasia or severe hypoplasia of the thymus gland and of the entire peripheral lymphoid system Thymic alymphoplasia is mainly transmitted as an autosomal recessive characteristic but there is evidence that it may be transmitted as an X linked characteristic [38] Peripheral lymphocytes from patients with thymic alymphoplasia cultivated with PHA fail to multiply and/or differentiate [28] In short, these individuals in addition to their inability to produce antibody are incapable of developing delayed hypersensitivity they are incompetent in both humoral and cellular resistance It should be pointed out however that patients have been described with proved thymic alymphoplasia in whom the values of all Igs were normal, [9 15 33] one patient had a normal number of plasma cells normal IgM but no IgG or IgA [14].

These patients form a third class of immunologic incompetence they do not develop delayed hypersensitivity or reject homografts which implies that their lymphocytes are immunologically incompetent, they are deprived of the ability to develop cellular resistance although they do possess plasma cells and may produce sufficient amounts of all or some Igs.

Another variant of immunologic incompetence associated with dysplasia of the thymus gland is that described in patients with ataxia telangiectasia or the Louis-Bar syndrome [13 35] These patients have no IgA but their IgG and IgM are normal or nearly normal In some cases more pronounced hypogammaglobulinemia or even agammaglobulinemia has been revealed by paper electrophoresis. Autopsy findings are variable—actually no more than 10 or 15 cases have been autopsied until now In most instances the thymus was dysplastic with few if any Hassal's corpuscles. The entire lymphoid tissue was poorly developed with few and small lymph follicles. Most of these patients died before they reached adult life following severe infection. The absence of IgA does not appear to account—at least mainly—for susceptibility to infection in these patients A broad spectrum of immunological deficiencies both humoral and cellular would appear to offer a more plausible explanation for their proneness to infection. Cellular immunity may be incomplete as shown in two patients who rejected skin homografts poorly and developed a sluggish hypersensitivity reaction. Interestingly these two patients, although possessing normal amounts of IgG and IgM, developed an incomplete antibody response when challenged with diphtheria tetanus pertussis or typhoid antigens and they developed no antibody response to viral antigens [30]

This form of immunologic incompetence associated with ataxia telangiectasia may be in a way similar to that in patients

with thymic alymphoplasia but normal Ig levels. There is considerable evidence that the thymus not only supplies peripheral lymphoid organs with immunologically competent cells, but also elaborates through its reticular epithelial cells a factor(s) necessary for the normal immunologic development of exothymic lymphocytes [24]. The presence of a dysplastic thymus implies a defect in a very early stage of the evolution of the immune mechanism. This may involve, to a different degree, both the development of the thymus, and hence the immunologic competence of the circulating lymphocyte and the biochemical maturation of the plasma cell which may elaborate normal amounts of immunologically inefficient gamma-globulin. This, of course, is merely a hypothesis which must await proof, but it appears to fit very well with the expression of immunologic deficiency in these patients.

The various immunologic deficiencies have been summarized in table 2. Patients with the pure Bruton type of agammaglobulinemia do not appear to be at risk, if vaccinated with vaccines containing toxoid, killed bacteria or even living attenuated bacteria [17]. Since they are unable to produce detectable antibody, their only danger following diphtheria or tetanus toxoid vaccination, for example, lies with the fact that they have acquired no immunity at all, in spite of their vaccination.

Most if not all BCG vaccinated agammaglobulinemic children develop tuberculin hypersensitivity and acquired resistance to tuberculosis [19]. Furthermore, with few exceptions these children have been vaccinated against smallpox with no untoward reaction. *Both* primary takes and accelerated reactions have been observed and, although antibodies do not appear in the serum following vaccination, these chi

dren develop delayed hypersensitivity to heat-killed vaccinia virus [17]

BCG vaccination is a very safe procedure and millions have been inoculated. However there are 9 cases described in the literature [1 2 3 4 6 12 16 24 32 43 45] who died of generalized BCG infection in most instances a few months after vaccination. Some authors who reported such cases thought they were associated with the agammaglobulinemia observed in their patients. Others attributed death to some obscure inherent or acquired impairment of the host's immunologic response However no satisfactory explanation had been offered for these fatalities until very recently Matsaniotis and Economou Mavrou reinvestigated the case histories of all patients reported to have died of generalized BCG infection [29 30] The following case report by Bouton *et al* is illustrative [3]:

This was a boy the first child of healthy parents. He had been BCG vaccinated at birth and was admitted to hospital at the age of six months because a swelling had appeared in the left axilla five days previously The lesion at the site of vaccination had developed when he was six weeks old and was still discharging The abscess was incised, a lot of green pus was evacuated but no organisms were cultured by routine methods. The patient was readmitted at the age of 9 months because his BCG ulcer and axillary sinus were still discharging A chest X ray showed diffuse miliary shadowing throughout both lungs.

His white cell count was 9 000/cmm with only 7% lymphocytes (630/cmm) His gamma-globulin was very low (0 21 g/100 ml) His Mantoux reaction was negative up to 1 100 u of O T Plasma cells could not be found in the bone marrow A second gamma-globulin determination gave 20 mg/100 ml In spite of antituberculous and gamma-globulin therapy the patient died on the day of admission.

At autopsy the tonsils were very hypoplastic. There were no adenoid and no carinal lymph nodes. Miliary nodules were found scattered throughout the lungs, the spleen and the left adrenal. In the mesentery small lymph nodes were found

On microscopic examination the miliary nodules consisted almost entirely of epitheloid cells. There was no necrosis, caseation or cuffing by lymphocytes. Numerous BCG were found in the center of these nodules. The lungs showed the characteristic picture of pneumocystis carinii pneumonia. At the site of vaccination there was no caseation and hardly any cellular reaction except by macrophages. The axillary lymph nodes contained no lymphocytes. Lymphoid tissue was not found in the tonsils and the adenoids.

The remaining BCG fatalities were very similar Table 4 shows that, apart from two cases where the patients were 7 and 19 years old respectively at the time of vaccination, the patients were vaccinated as newborns or within the first 6 weeks of life and died as infants There were 5 males and 4 females With the exception of case 6 which will be discussed later all patients in whom pertinent information is available had profound peripheral lymphopenia—less than 2000/cmm and in about one half of the counts less than 1000/cmm The skin reaction to 100 u of O T was invariably negative showing that these patients were all uncapable of developing delayed hypersensitivity In three of the six babies the serum gamma globulins were absent or very low and in case 3 plasma cells were completely absent, which is indirect evidence that this baby also had hypo- or agammaglobulinemia. We do not know what the gammaglobulins were in case 1 and case 4 is the only case

with normal gamma-globulin levels. With the exception of case 2 in whom tubercles were detected at the site of vaccination and in the spleen, tubercles were not found in any of these cases.

Case 3 deserves special consideration. There is strong evidence that the family of this girl was affected by an inborn immunologic defect. Three of the four children died as infants, two of sepsis presumably one of generalized BCG infection. Nevertheless, this girl was the only BCG fatality who had no lesion at the site of vaccination and no regional complication. She was definitely not lymphopenic; she had specific granulation tissue but little if any tendency to tuberculoid structure and only faint cellular reaction. Another point deserving consideration is that in the course of two months her gamma-globulins are reported to have been absent, normal and very much decreased on three separate occasions.

Two more BCG fatalities have been described while this review was being prepared [26 44a] In both the thymus was extremely hypoplastic

The cardinal points in each of the BCG fatalities with the exception of case II were firstly the absence of tuberculin hypersensitivity secondly profound peripheral lymphopenia and thirdly inability to form tubercles. It is well established that in a very small minority of BCG vaccinated children a positive tuberculin reaction fails to develop These children, however develop increased resistance to tuberculosis, they are capable not only of forming tubercles but also of developing immunocytes in numbers which are closely comparable to those of children with a positive tuberculin reaction following BCG vaccination [7] Their lymphocytes respond to antigenic stimulation with tuberculin in in vitro cultures by proliferation and differentiation [7]

The tubercle is a typical defensive cellular structure In human beings it takes about four weeks for tubercles to be formed and for tuberculin hypersensitivity to develop in response to the penetration of the mycobacterium By this time the in vitro lymphocytic response to tuberculin—presumably reflecting the lymphocytes which become immunocytes specifically oriented against the mycobacterium and tuberculin—is maximal [27] On becoming an immunocyte the lymphocyte acquires immunologic memory It multiplies and differentiates under appropriate antigenic stimulation and this results in the rapid production of the same type of cells and in the acceleration of all phases of the chronic inflammatory infiltrate There are more cells and they accumulate more rapidly thus meeting the requirements of the general biological phenomenon of defense in a quicker and therefore better way This, in fact, is the only specific effect of antigen upon immunocytes which has been demonstrated conclusively [40] and actually it is the essence of cellular immunity

Very little is known of the factor(s) causing certain mononuclear phagocytes to cluster together as a nodular tubercle but it is rational to assume that under stimulation of antigen bearing cells, immunocytes which arrive at random agglomerate around these cells and begin to proliferate That immunocytes multiply locally is beyond reasonable doubt, for the tubercle continues to enlarge even after the blood supply to the area has been interrupted [30]

The foregoing discussion, together with the data collected from the BCG fatalities, strongly suggest that patients who died in infancy were all affected by congenital thymic alymphoplasia It is unfortunate that the thymus was examined at autopsy in only two cases [4 12] It was small, weighing respectively 1.5 and 6 g Its cortex was greatly reduced and the gland appeared to be composed largely of medullary tissue Hassal s corpuscles were almost completely absent We know nothing at all of the thymus in the remaining infants, but their inability to develop a positive tuberculin reaction or to form tubercles together with their persistent lymphopenia strongly suggest that had their thymus been examined its size and histology would have been characteristic of congenital thymic alymphoplasia [17].

The seven years old boy [32] and the young man [43 45] who died of general-

had BCG infection do not appear to fit into the syndrome of congenital thymic alymphoplasia. For one thing they both survived for a very long time: they must have been vaccinated against smallpox and most have contracted the common rural infections of childhood. How could their vaccination and their illnesses have been uneventful, if they were incapable of developing cellular resistance? Why then did they die of generalized BCG infection? Their primary lesion failed to heal, their tuberculin reaction did not convert, they were lymphopenic and incapable of forming tubercles. One possibility is that these two patients may have been affected by an acquired lymphopenic disorder. Waksman *et al.* [46] have shown that specific reduction in the number of peripheral lymphocytes in rats by means of antisera against lymphocytes can abolish the delayed hypersensitivity reaction against certain antigens. It would be very interesting to speculate whether a similar reduction of lymphocytes may occur in man as a result of anti-self reactivity. In any case, although the exact cause of fatal generalized BCG infection cannot be defined with certainty in these two cases, the evidence points to an immunologic disorder probably stemming from the thymus.

During the last 10 years, at least a dozen reports have been published describing death from progressive vaccinia in babies with agammaglobulinemia. Rosen and Janeway [37] reviewed these cases and pointed out that all cases in which pertinent information was given, infants dying from progressive vaccinia had profound lymphopenia. In one case it was noted at autopsy that the thymus was absent. They concluded therefore that these children all had thymic alymphoplasia to account for their deaths. Nevertheless, progressive vaccinia has also been observed in patients with Bruton-type hypogammaglobulinemia [15a].

Children with thymic alymphoplasia may be equally at risk if vaccinated with living attenuated viruses, such as the oral polio or the measles vaccine. To our knowledge there is only one case report of a boy who developed paralytic poliomyelitis 7 weeks after taking type 1 polio vaccine orally. This boy showed none of the features of thymic alymphoplasia. He was severely hypogammaglobulinemic and autopsy findings were consistent with those of Bruton's type of agammaglobulinemia [5].

Various attempts have been made to de novo institute immunological competence in patients with thymic alymphoplasia, thymic tissue and lymph nodes have been implanted, fetal liver cells, bone marrow and sensitized lymphocytes have all been given [23]. Neither of these procedures has been successful. And cases have been described with immunologic deficiencies in whom fatal aplastic anemia [21] or even pancytopenia [20] has developed following transfusion of viable leucocytes. These complications have been attributed to a graft-versus-host reaction, in other words to the effect of the transferred leucocytes which were accepted in the first place because of the host's immunologic incompetence [21].

The practical implications of this review are that although the safety of smallpox, BCG and oral polio vaccination cannot be contested, it should be recognized that in individuals with immunologic incompetence, especially of the cellular type, vac-

cination may be disastrous these individuals must be carefully sought for especially among the infant age group As a screening procedure infants with a history of repeated infection or persistent moniliasis should not be vaccinated with BCG smallpox or even oral polio vaccine until the diagnosis of thymic alymphoplasia can be excluded. This may be achieved by repeated counts of peripheral lymphocytes and, more safely by examination of lymphoid tissue obtained by rectal or lymph node biopsy

Disease may be an experiment of nature disease following vaccination is an experiment in which the participation of man is an overwhelming responsibility Every effort should be made to prevent death from procedures which are designed to prevent disease

these discoveries which not only were of importance to medicine, but set the stage for the breathtaking developments of molecular biology of recent years.

Garrod's work was far ahead of his time His colleagues respected him his students loved him, his peers elected him to be the successor of Osler's prestigious chair at Oxford, but no one realized the general significance of his work. Even geneticists who should have known better ignored him and the literature on physiologic genetics of the 1920's and 1930's fails to mention him. Beadle's and Tatum's work which firmly established the one gene-one enzyme hypothesis was carried out in ignorance of Garrod's contribution.

Investigations on sickle hemoglobin

It took another discovery to establish biochemical genetics as a discipline of great relevance to medicine. In 1945, Pauling, the famous chemist, and Castle the renowned hematologist, served on a committee dealing with matters of national scientific policy Castle told Pauling that red cells from patients with sickle cell anemia when deoxygenated became sickled and showed birefringence in polarized light suggesting some type of unspecified molecular realignment Pauling later concluded that molecular abnormality of hemoglobin might best explain these phenomena and suggested to Harvey Itano, graduate student with medical degree, to investigate this problem. After much hard work and many negative findings, it became clear in 1949 that the electrophoretic mobility and, therefore the structure of hemoglobin of patients with sickle cell anemia was indeed different from that of normal hemoglobin. The somewhat puzzling genetic findings that parents of patients with sickle cell anemia were clinically well but had sickled red cells, was explained by finding both normal and abnormal hemoglobin in their blood [2]. Jim Neel's genetic conclusions (1949) [3] indicating that sickle cell anemia required the double dose of the sickling gene were confirmed by the biochemical data. Pauling realized the full general significance of these discoveries and pointed out that sickle cell anemia was the first example of a molecular disease.

The nature of the molecular abnormality in sickle cell anemia was not clarified until 1957 [4] Ingram a young biochemist, worked in the intellectually stimulating atmosphere of the Cambridge Laboratory of Molecular Biology Here, Sanger had established the amino acid sequence of insulin. Crick and Watson had demonstrated the double helix of DNA and Perutz and Kendrew were investigating the three-dimensional structure of hemoglobin and myoglobin. (By 1964 all these investigators had received Nobel prizes for their work) By digesting hemoglobin and separating the resultant peptides by various techniques, Ingram showed that the sickle hemoglobin molecule differed from that of normal hemoglobin by the substitution of only a single amino acid.

The stage was now set for a clear understanding of the nature of mutational alterations of protein molecules. Later work with bacterial tryptophane synthetase by Yanofsky and his group [5] confirmed what appeared evident when single amino acid alterations were found in many other abnormal hemoglobins. Amino acid alterations of the protein chain had a linear relationship to the mutational sites within

Biochemical Genetics in Medicine

Origins of human biochemical genetics

Many advances in science have occurred by applying concepts and techniques from different disciplines to an unsolved problem Garrod a British physician, worked on various rare metabolic diseases such as alkaptonuria in the early part of this century He was struck by the familial nature of this disease and noted the increased frequency of first-cousin marriages among the nonaffected parents of his patients. Talking matters over with Bateson, the biologist who coined the term of genetics, these findings seemed best explained by the recently rediscovered Mendelian laws Thus, each parent of an alkaptonuric patient was assumed to be a latent or recessive carrier of the gene for alkaptonuria, having derived this gene from a common ancestor The double dose of a specific factor produced the disease rather than consanguinity by itself Under the influence of the physiologic chemist Fredric Gowland Hopkins and arguing from alkaptonuria pentosuria cystinuria and albinism Garrod concluded that normal metabolism was carried out by single discrete steps each probably under the control of specific hereditary factors. Blocks at some particular point of intermediate metabolism due to congenital deficiency of an enzyme would lead to excretion or accumulation of normal intermediates which ordinarily could not be detected. Garrod named disorders of this sort inborn errors of metabolism and ascribed a more general biologic significance to these diseases [1] He maintained that just as structure varied between individuals biochemical variability was likely He predicted that idiosyncrasies to drugs as well as various degrees of natural resistance against infections might be explained by the 'failure of members of a species to conform to an absolutely rigid standard of metabolism How happy Garrod would have been to learn that an enzyme deficiency of the red cell (G6PD deficiency) predisposes to hemolytic reactions by drugs and at the same time confers resistance against falciparum malaria! Garrod utilized concepts from biochemistry and genetics and applied them to human disease to found the field of biochemical genetics We can be proud that a physician—a true clinical investigator—made

hemoglobin chains to the heme group. Hemoglobin is oxidized to methemoglobin at all times, but the physiologic reduction machinery of the red cell normally reduces the methemoglobin formed. The various types of Hb M resist reduction since the mutationally introduced tyrosine residues form a stable complex with the ferric ion of the heme group, so that methemoglobinemia and cyanosis result.

Polycythemia caused by an abnormal hemoglobin [9]. An abnormal hemoglobin was discovered in a family with mild polycythemia. Heterozygotes had clinical symptoms. This hemoglobin—Hb Chesapeake—was found to have an arginine→leucine substitution at the 92nd amino acid residue of the α chain, 5 amino acid residues away from the heme-linked histidine of the α chain. Hb Chesapeake showed a significantly increased oxygen affinity in red blood cells, as well as in the purified state which presumably explained the polycythemia. Neither methemoglobin nor increased blood destruction was found in Hb Chesapeake patients. Other cases of benign familial polycythemia may be caused by this type of abnormal hemoglobin.

Unstable hemoglobin diseases associated with hemolysis [10]. Occasionally an amino acid substitution may not grossly interfere with function, but may make the hemoglobin molecule more unstable. Blood destruction may follow. Several families with unexplained familial hemolytic anemia were found to have such unstable hemoglobins. In Hb Zurich the molecular site of substitution was identical to that in Hb M Saskatoon, the heme-linked histidine at the 63rd position of the β chain (his→arg). Patients with Hb Zürich are heterozygotes with chronic compensated hemolytic diseases. Affected patients develop severe hemolytic crises upon administration of a variety of oxidant drugs such as various sulfonamides. Severe methemoglobinemia occurs during the hemolytic crises, but is absent at other times.

Patients with Hb Seattle have chronic hemolytic diseases. The hemoglobin substitution affects position 70 or 76 of the β chain (ala→glu). Methemoglobin is not seen, but red cells from patients with Hb Seattle disease and Hb Zürich disease can be induced in vitro to form methemoglobin more readily than normal red cells. In both Hb Zürich and Hb Seattle the abnormal hemoglobin comprises more than 30% of the total hemoglobin. In a variety of other families with hemolytic anemia small amounts of highly unstable hemoglobins have been detected. The amount of these hemoglobins has comprised 10% or less. In several of these families many inclusion bodies have been detected particularly after splenectomy. The inclusion bodies may represent free α chains, such as has been detected in the hemolysates of patients with unstable β chain hemoglobin anomalies, such as Hb Köln, Hb Seattle and Hb St. Mary's. In another abnormal hemoglobin of this sort—Hb Ube-1—the investigators believed that the abnormality consisted of loss of reactivity of the sulfhydryl group at position 93 of the β chain.

Hb St. Mary's is associated with compensated hemolytic diseases. Although the specific site of the abnormality has not been identified yet, it is likely that the substitution affects the critical site of the hemoglobin molecule, since the absorption spectrum of Hb St. Mary's was abnormal.

the gene specifying the information for a given protein chain. Analysis of these chains could provide detailed information *regarding the site of mutation in the DNA* of the gene. Genes specifying the sequence of amino acids in protein chains were termed structural genes and the most common mutational alterations of protein were single amino acid substitutions.

Study with microorganisms yielded full understanding of the genetic code. Triplets of nucleotide bases contain information specifying which of the 20 amino acids is inserted into a protein chain and the composition of these DNA triplets has become recently clarified. All known amino acid substitutions in human hemoglobin can be explained by alterations of one of three nucleotide triplets which comprise the various coding units as worked out in microorganisms [6]. These findings conform to data on mutagenesis in lower forms of life and are of great biological importance in indicating that the genetic code is universal and applies to organisms as far apart as man and viruses.

Hemoglobin was found to be composed of four polypeptide chains. Two of the four hemoglobin chains were different and were described as the α and β chains. Each chain was found to be under control of a specific gene, the Hb α and Hb β genes. This finding has general significance for protein structure. Work with other proteins in recent years has shown that many proteins consist of several polypeptide chains and therefore require more than one gene for their *synthesis*. The one gene–one protein hypothesis has become the one gene–one polypeptide chain hypothesis.

Abnormal hemoglobins—A model of molecular disease [7]. Hemoglobin can be obtained freely from blood and many investigators all over the world initiated studies and surveys on hemoglobins. Within a few years it became clear that there was considerable biochemical variability of the hemoglobin molecule. Most hemoglobin variants were not associated with disease. If an amino acid substitution affects a portion of the molecule not involved in its physiologic function, i.e. oxygen carriage, altered electrophoretic mobility might result, but if the stability of the molecule is not otherwise impaired, the altered hemoglobin may carry out its usual function. However, a variety of hematologic diseases were found with amino acid substitutions near the critical functional site of the hemoglobin molecule, i.e., near the insertion of the heme group. These include positions 51–76 and 80–94 of the α chain and 57–76 and 85–96 of the β chain.

Hb M [8]. Chronic methemoglobinemia is one type of disease produced by amino acid substitution in the critical area of hemoglobin. Several abnormal hemoglobins producing methemoglobinemia and cyanosis exist. Clinical manifestations are observed in heterozygotes. Both α and β chain mutations producing Hb M have been found. In Hb M Boston and Hb M Iwate, histidine residues at the 58th and 87th positions of the α chain are changed to a tyrosine residue. An identical interchange has occurred at the 63rd position of the β chain to produce Hb M Saskatoon. Hb Milwaukee 1 is caused by a val→glu substitution at the 67th position of the β chain. It is noteworthy that positions 58 and 87 of the α chain and [redacted] of the β chain represent the points of attachment of the

hemoglobin chains to the heme group. Hemoglobin is oxidized to methemoglobin at all times, but the physiologic reduction machinery of the red cell normally reduces the methemoglobin formed. The various types of Hb M resist reduction since the mutationally introduced tyrosine residues form a stable complex with the ferric ion of the heme group, so that methemoglobinemia and cyanosis result.

Polycythemia caused by an abnormal hemoglobin [9]. An abnormal hemoglobin as discovered in a family with mild polycythemia. Heterozygotes had clinical symptoms. This hemoglobin—Hb Chesapeake—was found to have an arginine→leucine substitution at the 92nd amino acid residue of the α chain, 5 amino acid residues a ay from the heme-linked histidine of the α chain. Hb Chesapeake showed a significantly increased oxygen affinity in red blood cells, as well as in the purified state which presumably explained the polycythemia. Neither methemoglobin nor increased blood destruction was found in Hb Chesapeake patients. Other cases of benign familial polycythemia may be caused by this type of bnormal hemoglobin.

Unstable hemoglobin diseases associated with hemolysis [10]. Occasionally an amino acid substitution may not grossly interfere with function, but may make the hemoglobin molecule more unstable. Blood destruction may follow Several families ith unexaplined familial hemolytic anemia were found to have such unstable hemoglobins. In Hb Zurich, the molecular site of substitution was identical to that in Hb M Saskatoon, the heme-linked histidine at the 63rd position of the β chain (his→arg). Patients with Hb Zürich are heterozygotes with chronic compensated hemolytic diseases. Affected patients develop severe hemolytic crises upon administration of a variety of oxidant drugs such as various sulfonamides. Severe methemoglobinemia occurs during the hemolytic crises, but is absent at other times.

Patients with Hb Seattle have chronic hemolytic diseases. The hemoglobin substitution affects position 70 or 76 of the β chain (ala→glu). Methemoglobin is not seen, but red cells from patients with Hb Seattle disease and Hb Zürich disease can be induced *in vitro* to form methemoglobin more readily than normal red cells. In both Hb Zurich and Hb Seattle the abnormal hemoglobin comprises more than 30% of the total hemoglobin. In a variety of other families with hemolytic anemia, small amounts of highly unstable hemoglobins have been detected. The amount of these hemoglobins has comprised 10% or less. In several of these families, many inclusion bodies have been detected particularly after splenectomy The inclusion bodies may represent free α chains, such as has been detected in the hemolysates of patients with unstable β chain hemoglobin anomalies, such as Hb Koln, Hb Seattle and Hb St. Mary's. In another abnormal hemoglobin of this sort—Hb Ube-1—the investigators believed that the abnormality consisted of loss of reactivity of the sulfhydryl group at position 93 of the β chain.

Hb St Mary's is associated with compensated hemolytic diseases. Although the specific site of the abnormality has not been identified yet it is likely that the substitution affects the critical site of the hemoglobin molecule since the absorption spectrum of Hb St Mary's was abnormal.

In Hb Köln, the abnormality was localized between the 83rd and 120th amino acid of the β chain [11]

The more unstable the abnormal hemoglobin the more difficult will it be to detect small quantities of the mutant hemoglobin in the blood. Heat instability has been seen in most of the unstable hemoglobins and may represent a good screening test for such disorders. Unfortunately this test will not be infallible since an innocuous hemoglobin abnormality—Hb Tacoma (β^{30} arg→serine) has also been associated with heat lability [12]

Sickle cell disease. The red cells of heterozygotes with sickle cell disease can be made to sickle *in vitro* but such carriers are quite well under most circumstances since more than 50% of their hemoglobin is of the adult normal type. With severe hypoxia such as at altitudes over 12 000 ft *in vivo* sickling may occur and splenic infarction may be observed. The unusual circulation of the kidney leads to hemoconcentration and relative hypoxia and may produce renal sickling and hematuria in the absence of structural renal abnormalities. Patients with homozygous sickle cell anemia have no normal adult hemoglobin and will exhibit *in vivo* sickling with resultant organ damage and chronic hemolytic disease The mechanism by which a substitution of a single amino acid produces severe deformities of red cell shape is believed to be stacking of sickle hemoglobin molecules [13]

Most other hemoglobin abnormalities have not produced any disease in the heterozygote state presumably because the mutants interfered with neither stability nor function of the hemoglobin molecule The reasons for blood destruction in patients homozygous for Hb C, Hb E and Hb D diseases are not yet apparent.

The thalassemias [14] In this group of diseases the genetic mutation leads to depressed synthesis of a given hemoglobin chain, i e α or β thalassemia, and causes reduction in the amount of hemoglobin in the red cells. Heterozygotes usually have only mild anemia but homozygotes may be severely affected. The genetic mechanisms causing suppression of the hemoglobin genes are largely unknown.

However one type of thalassemia could clearly be related to an unusual type of abnormal hemoglobin—Hb Lepore. This hemoglobin is a fusion gene product consisting of both δ and β hemoglobin chains. The δ chain is a physiologic gene product differs by only 9 amino acid substitutions from the β chain and forms the two non α chains of a minor normal hemoglobin. Hb A_2. The δ gene is closely linked to the β gene Nonhomologous crossing-over between the β and δ gene produces a deletion of a portion of the δ and β chains with formations of a hybrid $\delta\beta$ polypeptide. Hemoglobin synthesis of the hybrid $\delta\beta$ molecule proceeds at a reduced rate similar to that of the normal δ chain which only comprises 2% of the total hemoglobin and thalassemia results.

Since hemoglobin can be easily obtained and analyzed the correlation of structure and pathologic function has progressed further than for other genetic diseases. Certain generalizations can be made Variability of molecules is likely to exist for other proteins and enzymes Occasionally a molecular abnormality may be of selective advantage to its carriers and its frequency will become significant Since the

sickle cell trait confers resistance against falciparum malaria, the frequency of that trait is relatively high in areas of the world where this type of malaria was endemic, even though the homozygous state was relatively lethal. The selective advantage of other genetic traits is less well understood, although malaria is likely to explain the relatively high frequency of the thalassemias. When the active or critical site of molecule or its stability is affected, disorders of function may be expected, such as various anemias, polycythemia and methemoglobinemia in the case of the hemoglobin mutations. Physicians will see more of the disease-producing mutations. However if whole populations are screened, benign and harmless mutants will be more common.

Glucose-6-phosphate dehydrogenase deficiency of the red cell—A model for inborn errors of metabolism. Enzymes are proteins and the general lessons provided by hemoglobin disorders should apply to enzymatic abnormalities. Mutational effects might change the configuration of an enzyme and distort the active site of the enzyme or interfere with the stability of the enzyme. The active site might be directly affected. Cofactors might not be able to bind properly or subunit association or dissociation might be interfered with. Unfortunately the amount of enzyme which can be recovered for protein studies is very small, so that basic knowledge regarding the nature of the biochemical abnormalities is less advanced than that of abnormal hemoglobins. However enzyme deficiency has been demonstrated in many disorders already.

Red cell enzymes are more readily available than most other material and more detailed knowledge is available in this area. Abnormalities of G6PD are a good example. G6PD deficiency of the red cell is a heterogeneous disorder. Many different mutations may cause alterations in G6PD activity [15]. Some mutations change the electrophoretic mobility of the enzyme and do not cause enzyme deficiency. They are clinically asymptomatic. Others cause enzyme deficiency but are clinically harmless unless certain drugs or fava beans are administered and then hemolytic anemia develops. A different mutation causing G6PD deficiency exists among Mediterranean and African populations. The Mediterranean mutation produces a more severe type of enzyme deficiency with a wider spectrum of drug sensitivity than seen among Africans. Recent studies in our laboratory [15a] have helped to define the nature of the biochemical lesion in the African type of G6PD deficiency (A −). When red cells were fractionated by age it could be shown that very young cells from deficient subjects had almost identical enzyme activity as compared with normals. Enzymologic properties were normal. Serologic activity of mutant G6PD (A −) as assayed by neutralization of antibody prepared against purified normal G6PD also was normal. Column chromatography however showed structural differences when the A − mutant was compared with normal and with the electrophoretically identical mutant with normal enzyme activity (A +). These findings may be interpreted to indicate that a structural mutation leads to more rapid degradation of the enzyme during red cell ageing. Since the normal enzyme is a hexamer the process may well relate to increased subunit dissociation. In contrast, the Medi-

terranean type of mutation was shown to exhibit already diminished activity in young red cells and exhibited grossly altered serologic activity. Its abnormal kinetic properties as well as its chromatographic properties clearly establish this mutant as another structural abnormality.

Other *mutations* are associated with chronic hemolytic disease in the absence of any drug or food administration. Chemical studies have shown that even *in vitro* a highly unstable enzyme is found in patients of this type.

The relatively high frequency of G6PD enzyme deficiency in Africans and Mediterranean populations appears to be caused by a protective advantage against *falciparum* malaria [16]. The discovery of G6PD variations of the red cell illustrates that abnormality affecting a single enzyme explained diverse types of hemolytic anemias, such as hemolytic disease of the newborn, drug induced hemolytic anemia, food induced hemolytic anemia, hemolytic anemia by infection, and chronic *non* spherocytic hemolytic disease. Apart from G6PD deficiency other enzyme deficiencies affecting the red cell have been discovered to cause hemolytic anemia. These include pyruvic kinase deficiency, triose phosphate isomerase deficiency and hexokinase deficiency. *All of them* are inherited as autosomal recessive traits.

Control mutations in man! The discovery by Jacob & Monod [17] of a class of mutations in microorganisms causing interference with genetic regulatory elements rather than with structural enzyme protein has elicited much interest and was recently rewarded with a Nobel prize. If such mutations existed in man, one would expect severe enzyme or protein deficiency. Since regulatory mutations affect the function of linked structural genes, several related enzymes or proteins might be affected. The structure of the affected protein or enzyme would be normal. Increased rather than deficient enzyme activity also might be explained by controller mutations, although structural mutations at allosteric sites of an enzyme, making it less responsive to *inhibition* by small molecules, would be an alternative explanation. Many *inborn* errors in man have been ascribed to regulatory mutations but *none have* been proven yet. In several instances, where a regulatory mutation was postulated, more detailed study revealed a structural mutation such as in the African type of G6PD deficiency cited above. Increased pseudocholinesterase activity [18] *in a family* was shown to be associated with an electrophoretically demonstrable structural mutation rather than with a control mutation.

However, three diseases remain where a good case can be made for the existence of regulatory mutations. In one type of hereditary persistence of fetal hemoglobin (African type) there is complete suppression of the adult type β and δ hemoglobin chains which is fully compensated by fetal (γ) chain production. In another type (Greek) there is only partial suppression of β and δ chain production with smaller amounts of fetal (γ) chain synthesis. The African type could be explained by complete deletion of the adjacent β and δ genes. This explanation, however, is inadequate for the Greek type of this syndrome and an operator type of mutation suppressing the linked β and δ structure genes could well explain both conditions [14].

In orotic aciduria two enzymes, orotidylic pyrophosphorylase and orotidylic

decarboxylase, are depressed to 50% of their normal enzyme activity in the blood cells of heterozygotes. Since the two enzymes are closely linked in E. coli they might also be genetically linked in man and both be depressed by a control type of mutation [19].

In acute intermittent porphyria increased δ-amino levulinic synthetase activity has been demonstrated. A control type of mutation has been postulated [20], particularly since increased activity of this enzyme can be induced experimentally by the same drugs which precipitate the man disease in genetically predisposed riers. Structural studies on the human zyme, ho ever have not yet been car ed out, and a structural mutation is not led out.

Pharmacogenetics—Enzymatic variability as model for human susceptibility. Several xamples of genetic disorders which predispose to drug reactions have already een mentioned. Thus, Hb Zürich and 6PD deficiency of the red cell both redispose to drug induced hemolytic nemia.

It has become clear that some drug eactions and a good amount of variability in response to drugs may be caused by genetically determined biochemical differences bet een individuals [21]. Prolonged pnea following administration of succinylcholine is often caused by genetic alterations of *pseudocholinesterase,* the enzyme which normally inactivates succinylcholine. Several different mutants affecting pseudocholinesterase have been recognized. The most common type is found in 3–4% of the population, who are heterozygous for this trait, and represents a structural mutation of the pseudocholinesterase molecule. About 1/2,000 individuals are homozygotes. A rare mutation presents with no enzyme activity and is known as the silent allele. Heterogeneity again has been found in several cases presenting with no enzyme activity. In some cases, cross reactive material could be found. Sera with cross reactive material might represent examples of control mutations, but other explanations could also be offered for those findings. Individuals who are homozygous for the different pseudocholinesterase mutations, as well as mixed heterozygotes for two different mutations (such as those carrying the enzyme for the atypical common mutation, as well as for the silent mutation) were found to be drug sensitive. A simple screening test based on differential inhibition of the enzyme by enzyme inhibitors has been developed for use in agar gels [22] and has been extended for test tube use in our laboratory. Both heterozygotes and homozygotes can be detected.

Differences in biotransformation of isoniazid (INH) are caused by genetic differences in acetylation between individuals [24]. "Slow inactivators" of the drug ha e high blood levels, lack an acetylating enzyme in their livers and are homozygotes. Individuals who are heterozygotes have intermediate blood levels of the drug while homozygotes for the acetylating enzyme have low blood levels. Other drugs, such as some sulfa drugs, Hydralazine and Nardil, ppear to be inactivated by a similar mechanism. The frequency of peripheral neuropathy induced by INH is very much higher among slow inactivators than among rapid inactivators. The distribution of the various genetic classes is trimodal rather than unimodal when

appropriate tests are being used. There is a higher frequency of individuals with the acetylating enzyme in oriental populations. These findings are of general significance. Whenever a difference in drug response is seen between genetically differing populations and a discontinuous response is obtained when a sufficiently large number of individuals is studied, genetic differences can be expected.

Liver alcohol dehydrogenase is mainly concerned with breakdown of ethyl alcohol. The finding of an atypical alcohol dehydrogenase with higher *in vitro* enzymatic affinity for alcohol in some human liver specimens is of some interest [25]. Carriers of this mutation should be more tolerant of alcohol than the rest of the population. Many Japanese individuals react with marked vasodilation to the administration of alcohol. The mechanism is unknown and raises the question whether vasoactive peptides are released in these individuals. Further studies are indicated.

Drug resistance may be genetically controlled. Increased pseudocholinesterase activity is a rare mutation and causes succinylcholine resistance just as defective pseudocholinesterase activity causes succinylcholine sensitivity [18]. Marked resistance to the action of anticoagulant drugs, such as warfarin and dicumarol, has been observed as a rare mutation in one family [26].

The examples of genetically determined drug reactions may serve as models for the interaction of genetically determined biochemical variability with exogenous agents of disease. The enzyme abnormality alone is harmless as is the conventional dose of the drug. However, when the usual dose of the drug is given to an individual with enzyme deficiency, a drug reaction or disease occurs. Neither the genetic abnormality nor the drug alone cause difficulties. The administration of the drug to the genetically susceptible individual, however, causes disease. By analogy, other diseases may be caused by such interaction of environmental agents and genetic variability. In the more common diseases, however, more than a single enzyme abnormality may be expected, so that the constitutional basis of such diseases must be sought in the cooperation of several genetic factors rather than in a single specific enzyme deficiency.

Biochemical screening for inborn errors of metabolism [27, 28]. The brain is highly sensitive to various metabolic disturbances in the growing infant. Many different inborn errors of metabolism are associated with mental retardation. These include phenylketonuria, galactosemia, maple syrup urine disease, histidinemia, goitrous cretinism, homocystinuria, Hurler's syndrome, methemoglobinemia due to diaphorase deficiency, hyperuricemia associated with choreathetosis and self-destructive behavior, and several other amino acidurias. Mental retardation is also more common in some other hereditary disorders such as myotonic dystrophy, pseudohypertrophic muscular dystrophy, and neurofibromatosis. Although these conditions are not classified as inborn errors of metabolism, the existence of mental retardation suggests a more generalized systemic involvement affecting the brain.

In some diseases such as homocystinuria and methemoglobinemia due to diaphorase deficiency, mental retardation is only seen in some patients with the disease. The reasons for the presence or absence of

TABLE 1. *Urinary screening tests in some inborn errors of metabolism associated with mental retardation.*

Urine Test	Phenylketonuria	Histidinemia	Homocystinuria	Galactosemia	Tyrosinemia	Maple Syrup Disease	Hurler's Syndrome
Ferric Chloride Test	+	+	−	−	−	−	−
Cyanide Nitroprusside Test	−	−	+	−	−	−	−
Benedict Test	−	−	−	+	±	−	−
Nitrosonaphthol Test	−	−	−	−	+	−	−
Dinitro Phenylhydrazine Test	+	+	−	−	+	+	−
Cetyl Trimethyl Ammonium Bromide Test	−	−	−	−	−	−	+

mental retardation are not clear yet, but may be related to the interaction of the metabolic error with other genes predisposing to mental deficiency [24]. Prophylactic treatment involving dietary management is highly promising in phenylketonuria and galactosemia and theoretically helpful in maple syrup urine disease and homocystinuria. Early diagnosis is therefore mandatory so that treatment can be started as soon after birth as is possible. Bacterial inhibition assays are available for phenylketonuria, galactosemia histidinemia and maple syrup urine disease. The principle of these tests consists in suppression of growth of certain bacterial strains in the presence of some of the abnormal metabolites present in the blood of affected patients. Simple urinary screening tests are available to detect a variety of these disorders [28]. These tests can be done in any clinical laboratory and do not require specialized equipment (Table 1). Amino acid screening can be done chromatographically or with amino acid analysers in certain laboratories. Before potentially harmful treatment is started, consultation with a specialized laboratory is always indicated.

Several years ago, we developed a simple screening test for G6PD deficiency based on reduction of the dye brilliant cresyl blue [30]. The test has been widely used for the detection of G6PD deficiency but, along with other screening tests for this condition, must be used with caution during hemolytic episodes caused by the African type of G6PD deficiency when the older red cell population is destroyed and only young red cells remain in the blood. A normal screening test result may then be obtained in the presence of G6PD deficiency. A dye test based on the same principle has been devised by Beutler for galactosemia and may prove helpful in mass screening. Beutler recently also has developed simple fluorescence screening tests for the detection of red cell enzyme abnormalities which depend on conversion of the reduced pyridine nucleotides DPNH or TPNH to DPN or TPN.

It would be unwise at this time to pass laws regarding screening of all newborn babies for a variety of biochemical genetic diseases. Extensive studies need to be performed on an investigational basis to rule out some of the difficulties which may be expected in this work.

Carrier detection Population studies for gene frequencies and the requirements of genetic counseling make it desirable to have tests available for the detection of heterozygotes. If the enzyme or protein abnormality in a given disorder is known specific assays can be devised In general the enzyme level of heterozygotes is 50 % that of normals (acatalasemia methemoglobinemia due to diaphorase deficiency galactosemia pseudocholinesterase deficiency pyruvate kinase deficiency histidinemia) [31] This finding by itself is good evidence that regulation of enzyme activity occurs at the genetic level rather than by feedback inhibition. Overlap of heterozygote values with the normal range is observed in most disorders where enzyme activity was measured When a structural difference of the enzyme can be demonstrated as an essential part of the analysis (i.e. electrophoretic differences or the differential inhibition exhibited by pseudocholinesterase variants) such overlap disappears. The explanation for overlap between normals and heterozygotes on enzyme activity assays presumably relates to the existence in the normal population of several genetically differing enzymes with variable enzyme activity in the normal range [32] There is excellent proof for the existence of such isoalleles in the case of red cell acid phosphatase and highly suggestive evidence from correlation studies in relatives for glucose-6-phosphate dehydrogenase and pseudocholinesterase Other more indirect evidence suggests that the phenomenon of isoalleles may be quite general. When a heterozygote inherits a high capacity normal allele from one parent and a mutant allele with negligible activity from the other parent the level of enzyme activity in the heterozygote may be similar to that of normal individuals with two doses of low capacity isoalleles.

Carrier detection of autosomal recessive traits is genetically of great interest, but practically of less importance than detection of heterozygotes for X linked traits. The clinically normal sibs of patients with autosomal recessive disease have a 2/3 chance of being carriers. The chance that their mates are carriers equals the population frequency of the heterozygous state (i.e. 2% for phenylketonuria) Recurrence risk of the disease from such a mating is very low ($2/3 \times 1/50 \times 1/4 = 1/300$ for phenylketonuria) Sisters of patients with X linked diseases have a 1/2 chance of being carriers. If they are carriers, 1/2 of their sons will be affected—a much higher risk. Carrier detection of clinically important X linked diseases such as hemophilia and pseudohypertrophic muscular dystrophy has made some progress in recent years Antihemophilic globulin levels and creatine phosphokinase levels (as evidence of some muscle disease in clinically normal heterozygotes for muscular dystrophy) can be assayed. Apart from the potential problems posed by isoalleles, the effect of random inactivation of the X chromosome (Lyon hypothesis) adds a further complication to X linked carrier detection [33] According to this concept, approximately 1/2 of the maternal and 1/2 of the paternal X chromosomes in a given female are genetically inactive Depending upon the time of inactivation during embryologic development and depending upon possible selective mechanisms acting on these cell populations in later life, the ratio of active maternal to paternal chro-

zosomes may not be 50/50 but may range from 1/99 to 99/1. Consequently if in a given case most of the normal genes are active and the mutant genes are inactive, test results of such a heterozygote will fall in the normal range. However careful assay of a large number of known normals and obligatory heterozygotes should help to solve some of these problems and allow probability statements whether a given person with a value in the zone of overlap belongs to the normal or heterozygote population. Centralized specialized laboratories will be required for this important work.

Summary

1. The history of human biochemical genetics is reviewed with special references to Garrod's and Pauling's contributions.

2. Recent knowledge on the correlation of gene structure and protein structure is reviewed.

3. The influence of various mutations on the hemoglobin molecule is discussed. Heterozygote structural mutations affecting the critical active site of the hemoglobin molecule may lead to hemolytic anemia, drug sensitivity, polycythemia and methemoglobinemia. Other mutants are usually harmless. Another class of hemoglobin mutants—the thalassemias—cause diminished hemoglobin chain production and may lead to severe anemia in the homozygote state.

4. Many different glucose-6-phosphate dehydrogenase mutations have been discovered. Some are rare mutants, others are common and, as the sickle trait, owe their frequency to a selective advantage vis-a-vis falciparum malaria. The African type of G6PD mutant is caused by a structural mutation which causes more rapid degradation of the enzyme during red cell ageing. The chemically most unstable mutants are associated with chronic hemolytic disease.

5. Mutations of controlling elements as contrasted to structural mutations have not yet been proven in man, but hereditary persistence of fetal hemoglobin and orotic aciduria can best be explained by control mutations.

6. Differences in drug response and drug reactions may be caused by genetically determined biochemical variability. G6PD deficiency may cause drug hemolytic anemia. Pseudocholinesterase alterations may cause sensitivity or resistance to succinylcholine and differences in the acetylation of some drugs are genetically controlled.

7. Biochemical screening is feasible for a variety of disorders and is strongly indicated since certain forms of mental retardation may be prevented by early treatment, e.g. phenylketonuria.

8. Carrier detection of many heterozygote traits is possible. Overlap in enzyme activity between heterozygotes and normals may be caused by the existence of isoalleles in the normal population. Screening of heterozygotes of X linked diseases (muscular dystrophy and hemophilia) is practically more important in family counseling than screening for heterozygotes of autosomal diseases.

On The Changing Patterns of Pediatric Practice

by WALDO E NELSON[1]

Pediatrics as an important section of medical practice had its inception during the latter half of the nineteenth century At this time the principal concern was with physical illness and more with acute illness than with chronic disorders. The reasons were obvious. Morbidity and mortality rates at all ages of infancy and childhood, and especially within the first few years of life were extraordinarily high It soon became evident that reduction in the high incidence of infections and of nutritional diseases by preventive means had much greater potential for improving the child health situation than did currently available therapeutic facilities. It is noteworthy that in the leading textbook of Pediatrics (Holt) at the turn of this century there is no consideration of behavioral disorders.

The significant reductions in morbidity and mortality rates among infants and small children in the first twenty years or so of this century were undoubtedly due to a variety of factors, not all of which can be classified as medical or credited to the medical profession. In the main, the beneficial features were preventive and not curative in nature In addition to prevention of diphtheria and smallpox by specific immunization, of rickets and scurvy by specific nutritional supplements, and of infantile diarrhea in artificially fed infants by simple sterilization of their milk feedings, there were the general improvements in community sanitation and living standards. It is thus not difficult in retrospect to understand why the 1930's ushered in an era of therapeutic nihilism and attention was increasingly directed to a search for specific causes of diseases and to an understanding of the pathologic physiology which characterized them This too was the time of the first concentrated efforts to add guidance in child rearing to pediatric practice

The introduction of sulfanilamide in the mid thirties as the forerunner of specific antimicrobial agents and the subsequent isolation of corticotropin and the corticosteroids as well as the development of a wide variety of other effective therapeutic agents has restored drug and biologic therapy to an important place in medical practice but this time on bases much more substantial than had been conceived possible by most observers.

With the great reduction in serious illnesses among infants and children, the time and efforts of pediatric personnel began to be directed more intently to chronic diseases physical handicapping

[1] Professor of Pediatrics.

and mental retardation. These disorders which had received little attention have now come to be one of the major components of pediatric practice.

During the span of a century or so the pattern of pediatric practice has changed materially and especially so in North America. It is of interest that the patterns of pediatric practice which have evolved in the United States and Canada have differed rather significantly from those of many of the European and Asian countries, and to some extent from those of the South American ones. In the former the general pediatrician has become in large measure a general practitioner for children with heavy emphasis on the medical care of infants and young children rather than of the older ones. Since such care in recent years has consisted mainly of supervision of minor illnesses and of guidance in child rearing, the pediatrician in some respects is becoming as much or more oriented to the mother as he is to the child himself. By contrast, in many of the European countries the pediatrician serves mainly as a consultant to the general practitioner in the management of the more serious and/or more complex pediatric problems. Hence, in these countries the pediatrician remains somewhat more disease-oriented. But in all countries there has emerged a great interest in the various subspecialties of pediatrics such as neurology endocrinology hematology and psychiatry and a large number of comparatively recently trained physicians have elected to limit their medical activities to one of the relatively large number of subspecialties. Such physicians are now principally located in medical centers affiliated with medical schools.

The issue at the moment is not whether the practices of pediatrics have changed or are changing They have and are The issue at the moment is not even so much the current direction of change, but rather how extensive these changes will be how rapidly they can be accomplished with currently available personnel, and in what ways and to what extent educational programs should be altered to prepare medical and paramedical personnel for these prospective roles.

Critical to such planning is the recognition that pediatric needs differ sharply among peoples in high and low socioeconomic classes. While it is common to make such distinctions between peoples in the so-called privileged and underprivileged countries, it is just as necessary to be aware that such distinctions exist in significant measure within practically all countries, perhaps all save the smaller northern and western European countries. The great trend to urbanization has transferred much of the poorer rural population and added them to the slum dwellers of our larger cities. Unfortunately in the United States the majority of recently trained pediatricians who have gone into private practice have settled in the suburban areas where they can develop a busy practice among families of good socioeconomic status. Such practice can currently be quickly established and is relatively lucrative. As a consequence, the bulk of the people with low financial income and of poor educational status who have the greatest needs for health services and for guidance in health practices are inadequately served.

Until comparatively recently the private practice of medicine including that

of pediatrics, has been on a distinctly solo or individualistic basis with the majority of physicians being in the category of general practitioners The pattern has changed markedly and will probably continue to change Combinations of two or more doctors whose practice is limited to the same specialty was the first major step away from solo practice Then came medical centers to which the private physician could refer his diagnostic and therapeutic problems Those have been mainly associated with and are an integral part of medical school hospitals. But there have been detached ones, of which the Mayo Clinic in rural Minnesota is the best known example The private clinic pattern of practice is now taking hold, and especially so in the western half of the United States. Such clinics tend to have physicians trained in most of the specialties of medicine and some even have their own hospitals In some payment is on a fee-for service basis and in some it is on an annual contract basis

Whether the private individual practitioner is destined for extinction is a matter of conjecture It would be unrealistic to think that the traditional pattern of medical practice will be erased precipitously Moreover it would be most unfortunate if the role of the old family doctor who at his best, was physician, family counsellor and community leader were to be eliminated Certainly it has become impossible to be all things medically for the family unit. In addition, the current instability of neighborhoods resulting from the frequent movement of families from community to community within a given city and between cities does not permit the development of a permanent clientele by very many physicians.

Nevertheless, it seems not only important but essential that we retain the personal relationship of patient (and family) with one physician who sees and understands the patient as a person within his own sphere—family and community Within limits this personal arrangement should be possible in group practice. But if it is to be the policy of permitting the individual to select his own general physician within the clinic group, and even to change from one to another must be firmly established from the outset.

From limited experience the deduction has gained support that the general practitioner as he has been known, has little or no place in a relatively large medical group which operates as a private clinic Apparently such physicians do not effectively or comfortably work in conjunction with those trained in the various specialties of medicine and, on the other hand are less apt to be selected by patients for their general care than are the pediatricians and internists. This experience and evaluation of it is in part responsible for the suggestion that the next step in medical practice should be the creation of a new type of general practitioner who has had specialized training in general pediatrics and in internal medicine and who then could serve as physician for all members of the family unit Like the family doctor of old he could manage the common illnesses, provide child guidance and family counseling and in addition select and support the specialist whenever specialized medical services were required.

An important question of the moment is to what extent can the medical services

of the physician be supplemented and complemented to make the most effective utilization of his skills and to provide the patient with services which are best rendered by persons with special training for them. Such persons are currently designated as paramedical personnel, ancillary medical personnel or medical assistants. The designation is important only as it conveys to those who give and to those who receive the services an adequate concept of and respect for the various roles. Such personnel currently include the office nurse, the home nurse (Public Health nurse), the social worker the psychologist, the health educator the occupational therapist the physical therapist, the audiologist, the speech pathologist and therapist, and the nutritionist. To what extent some of these roles can be combined in individuals who work within private medical groups and what new roles will be created is a matter of conjecture at the moment and will be determined by experience and leadership. There is little doubt in the minds of many of us, however that the potential for improvement of medical services lies as much in the effective use of such ancillary personnel as it does in increasing the number of practicing physicians—perhaps more so. In this respect the private practitioner can borrow from the experience of the well organized hospital clinic.

One natural outcome of such a concept of medical practice is the development of the team concept of medical practice, especially for the management of chronic and permanently disabling conditions and for the solution and management of the more complex medical problems. Because in some instances such practice has resulted in fragmentation of service for the patient and his family and is often not only incomplete but not adequately explained to and understood by them the term "team has come under criticism, in some of our better medical units in which team work is highly effective for the more involved situations and in which patients have a distinct sense that their problems are thoroughly studied and managed, it is studiously avoided. In a sense this is unfortunate, since exactly what is needed is team work in the most complete sense conceivable. The solution appears to be relatively simple the personnel who participate in a given patient's medical care must work as a team in the strictest sense. But the team must in every instance have a captain. This leader should be the physician. Unfortunately all too many physicians are not adequate for such a role. They lack the qualities of leadership necessary for the personnel group and they do not appreciate the essentialness of providing an understanding explanation to the patient and his family do not know how to provide it or will not take the time to do it.

Training for such comprehensive care is essential and should begin in the undergraduate phase of the physician's education and in that of all members of the allied professional groups. Obviously such training should continue in the immediate postgraduate phases and thereafter through on-the-job experience and, periodically through postgraduate short-term courses or institutes.

For general pediatric care a specially trained medical assistant might prove to be the most useful person to be added in the next phase of development of medical

of pediatrics, has been on a distinctly solo or individualistic basis with the majority of physicians being in the category of general practitioners The pattern has changed markedly and will probably continue to change Combinations of two or more doctors whose practice is limited to the same specialty was the first major step away from solo practice Then came medical centers to which the private physician could refer his diagnostic and therapeutic problems These have been mainly associated with and are an integral part of medical school hospitals. But there have been detached ones of which the Mayo Clinic in rural Minnesota is the best known example The private clinic pattern of practice is now taking hold, and especially so in the western half of the United States. Such clinics tend to have physicians trained in most of the specialties of medicine and some even have their own hospitals. In some payment is on a fee-for service basis and in some it is on an annual contract basis.

Whether the private individual practitioner is destined for extinction is a matter of conjecture It would be unrealistic to think that the traditional pattern of medical practice will be erased precipitously Moreover it would be most unfortunate if the role of the old family doctor who at his best was physician family counsellor and community leader were to be eliminated. Certainly it has become impossible to be all things medically for the family unit. In addition, the current instability of neighborhoods resulting from the frequent movement of families from community to community within a given city and between cities does not permit the development of a permanent clientele by very many physicians.

Nevertheless it seems not only important but essential that we retain the personal relationship of patient (and family) with one physician who sees and understands the patient as a person within his own sphere—family and community *Within limits* this personal arrangement should be possible in group practice. But *if it is to be* the policy of permitting the individual to select his own general physician within the clinic group, and even to change from one to another must be firmly established from the outset.

From limited experience the deduction has gained support that the general practitioner as he has been known, has little or no place in a relatively large medical group which operates as a private clinic Apparently such physicians do not effectively or comfortably work in conjunction with those trained in the various specialties of medicine and, on the other hand, are less apt to be selected by patients for their general care than are the pediatricians and internists. This experience and evaluation of it is in part responsible for the suggestion that the next step in medical practice should be the creation of a new type of general practitioner who has had specialized training in general pediatrics and in internal medicine and who then could serve as physician for all members of the family unit Like the family doctor of old, he could manage the common illnesses, provide child guidance and family counseling and in addition select and support the specialist whenever specialized medical services were required

An important question of the moment is to what extent can the medical services

well it may be. The principal issue is whether the individual should retain some portion of responsibility for the cost of his own medical care. Except in the case of the medically indigent family it is my thought that he should. This stand does not exclude government participation but it is against the complete transfer of individual responsibility and the development of the philosophy of the welfare state. The situation at the moment is not a simple one. The medical profession as a group in the United States has not followed a course which has met fully the needs of all people. Perhaps it would have been better had the medical associations worked more closely with governmental agencies. In an ideal society, presumably a goal of civilized peoples, medical care of the best type would be available to those unable to pay for it as well as to those who can. In spite of some claims to the contrary there are many deficits. Where the present programs within the United States will lead is, of course, a matter of conjecture. In the current situation the government is trying to do more than is possible with available manpower and is not taking time for careful long range planning. Responsible medical leaders of other countries should pay close attention to and profit from our mistakes and failures as well as successes. It is unfortunate when, as in our case, there is so much political motivation behind presumed social progress. Legislation in respect to health matters is patently most difficult to control and will require the emergence of concerted medical leadership of a high order if recent mistakes are not repeated and confounded by those with short-range, selfish interests for their own personal power or for the over-development of their own institutions.

Pediatrics can and should play an important role in the current social evolution. If the preventable ills of infancy and childhood are to be controlled—and they will be—and if the birth rates within all countries are to be reduced to appropriate limits—and they must be—and if man's personal ambitions could be satisfied without infringing on the opportunities of other men of whatever country—and they must be if civilized man's goals are ever to be attained—then the role of pediatrics may become a much more limited one.

At the moment, however, the challenge to pediatrics encompasses all aspects of child welfare except that of formal education, and, even here, there is need for collaborative efforts. The relationship of physical fitness to learning potential is obvious, and perhaps of equal importance is the opportunity for the pediatrician to provide counsel in the formulation of the school's curriculum in health education and to attune his personal instruction of the children in his practice with it.

It is to the broad aspects of child welfare that pediatrics must give increasing attention. No longer can the pediatrician assume that he alone is sufficient to provide the health services now potentially available. Nor is this possible solely by the combined efforts of child psychiatrists and other physicians representing the many subspecialties of pediatrics, such as the neurologist and the endocrinologist. Rather, to be as effective as seems possible the pediatrician must recognize that pediatrics *represents* but one segment of the several professional groups which are now concerned with and operative in child

care. Such a person should be able to serve effectively as a visiting nurse within the home for carrying out special procedures and for instructing the mother in preparation of the milk formula in feeding and in such techniques as the taking of temperature and the giving of an enema and also as a psychologist and social service worker in assisting in the instruction of the parents in the philosophies and practices of child rearing and in an appreciation of the wide range of normal physical mental and social development Such a person would in the strictest sense have to be an essential member of a team with the physician. one in which each would know in detail what the other was doing The training for such an assistant to the pediatrician would have to be specially devised. It would include enough of nursing care to provide competence in the more simple techniques and an understanding of the child s and family s reactions to illness, irrespective of its severity special training to provide an adequate concept of growth and development so that she could be interpretive and adaptive for the parents of the guidance given initially and repetitively by the pediatrician and education to provide a philosophy of social responsibility which is centered individually in the family as the basic unit and socially within the immediate community as the larger unit

It should seem quite evident that if pediatric care can be truly contributive in child rearing the qualitative and quantitative needs of children in the under privileged classes should be much greater than those of families more privileged in respect to educational and economic status. There are of course sharp contradictions. Nevertheless the generality holds and ways must be found to provide the best of general and specific medical care and guidance for children of all classes Within communities of the lower socioeconomic classes there are probably more opportunities for medical assistants of all categories and especially specialized personnel such as public health nurses, social workers, health educators, psychologists and the like but it also seems reasonable that the specially trained general pediatric assistant as just described, could also be a useful adjunct In such a situation she might well be an intermediary between the physician and the more specially trained ancillary medical personnel on the one hand and the patient and his family on the other

The economic aspects of such medical care are also a matter of concern. It is not possible here to consider the many ramifications and the arguments for and against individual responsibility in contrast to financial support by the state for medical care The author may express his opinion, however that adequate utilization of medical services which are wholly state-supported requires a degree of social development and sophistication among people who are financially independent which is far from being universally achieved. Man seems to grow and develop as he assumes and successfully accomplishes tasks involving increasing responsibilities. It may be that one of the essentials for good medical care is the desire of the individual for it There is no doubt that so-called third party financial participation in medical care be it by private or public agencies is now integrated into the economic structure of most countries. And

all it may be. The principal issue is whether the individual should retain some portion of responsibility for the cost of his own medical care. Except in the case of the medically indigent family it is my thought that he should. This stand does not exclude government participation but it is against the complete transfer of individual responsibility and the development of the philosophy of the welfare state. The situation at the moment is not a simple one. The medical profession as a group in the United States has not followed a course which has met fully the needs of all people. Perhaps it would have been better had the medical associations worked more closely with governmental agencies. In an ideal society presumably a goal of civilized peoples, medical care of the best type would be available to those unable to pay for it as well as to those who can. In spite of some claims to the contrary there are many deficits. Where the present programs within the United States will lead is, of course, a matter of conjecture. In the current situation the government is trying to do more than is possible with available manpower and is not taking time for careful long range planning. Responsible medical leaders of other countries should pay close attention to and profit from our mistakes and failures as well as successes. It is unfortunate when, as in our case there is so much political motivation behind presumed social progress. Legislation in respect to health matters is patently most difficult to control and will require the emergence of concerted medical leadership of a high order if recent mistakes are not repeated and confounded by those with short-range, selfish interests for their own personal power or for the over-development of their own institutions.

Pediatrics can and should play an important role in the current social evolution. If the preventable ills of infancy and childhood are to be controlled—and they will be—and if the birth rates within all countries are to be reduced to appropriate limits—and they must be—and if man's personal ambitions could be satisfied without infringing on the opportunities of other men of whatever country—and they must be if civilized man's goals are ever to be attained—then the role of pediatrics may become a much more limited one.

At the moment, however the challenge to pediatrics encompasses all aspects of child welfare except that of formal education, and, even here there is need for collaborative efforts The relationship of physical fitness to learning potential is obvious, and perhaps of equal importance is the opportunity for the pediatrician to provide counsel in the formulation of the school's curriculum in health education and to attune his personal instruction of the children in his practice with it

It is to the broad aspects of child welfare that pediatrics must give increasing attention. No longer can the pediatrician assume that he alone is sufficient to provide the health services now potentially available. Nor is this possible solely by the combined efforts of child psychiatrists and other physicians representing the many subspecialties of pediatrics, such as the neurologist and the endocrinologist. Rather to be as effective as seems possible the pediatrician must recognize that pediatrics represents but one segment of the several professional groups which are now concerned with and operative in child

welfare The challenge would appear to be whether these various groups—pediatrics, public health nursing social service health education psychology and other ancillary medical personnel—can coordinate their efforts in effective ways which will make their joint services available to the private pediatric patient as well as to the one who is currently dependent upon public health facilities The responsibility of leadership in such collaborative efforts would appear to be most logically placed in the hands of the pediatrician. The extent to which pediatrics accepts this responsibility throughout the world and the objectivity with which such cooperative efforts are directed and carried out may well be a determining factor in the improvement of child health in all countries

The Child with Down's Syndrome (Mongolism) His Parents, and the Community

by JAKOB ØSTER

Mongoloid children are from the very beginning quite special among the mentally retarded, they raise an immediate social problem, because the diagnosis can practically always be made at or shortly after birth. The characteristic appearance, possibly in association with chromosomal investigations, can establish the diagnosis with certainty to the experienced investigator. Even minor uncertainty should make the doctor refer the child to the expert, as diagnosis of Down's syndrome implies far-reaching consequences for both the child and the parents.

The first question to be considered is whether the parents should be informed. In my opinion the parents must be fully informed, as soon as the doctor is absolutely sure of the diagnosis, but it must be admitted that the communication is facilitated in the fortunately many cases, in which the parents themselves have suspicions that there is something peculiar about the behaviour of the child. From my own experience and investigations it is evident that the way of informing is at least just as important as the information itself. Extremes in the ways of informing the parents may be illustrated by the following examples: One doctor may say "A mongoloid of the worst type, prospects hopeless, send him away and forget him" another may say "Go home, love the child, and take care that you get other children". But none of these two methods is satisfactory. What many parents seem to miss is a sober statement of the condition, the possible cause; how a mongoloid child is; how the child may be expected to develop; whether the risk of having another mongoloid child is increased or not—and, after that, assistance and support, so that the parents may reach a well-considered decision on the solution of their problems.

The general improvement in the state of health and the decrease in mortality achieved in the last decades have been beneficial to the mongoloid children too. Certainly there are still many dying within the first years of life on account of congenital heart disease or infections to which many mongoloid children are predisposed. However, a recent English investigation has shown that four times as many mongoloids survived the first 10 years of life in 1959 as compared to 1929. There was a time when many parents were consoled by supposing that their mongoloid child would die early; this is no longer absolu

tely true thanks to therapy with antibiotics, which means that to-day there are perhaps more mongoloids in the community than before and that they have justified claims on the community

Why are mongoloid children weak? Predisposition to infections is presumably due to slow development bad respiration and difficulties in sucking and swallowing Mortality has proved to be different in mongoloids living at home from that in mongoloids placed in institutions. It is greatest in institutions, depending upon the degree of overcrowding and the available staff taking care of the children. This is partly due to the bigger risk of massive and recurrent infections, but also to psychic factors, because the child in an institution meets with a quite different way of life Similar problems arise when mongoloid children stay in hospitals we know that they behave and react quite differently from what they do at home and that under this psychic stress a restraint of all their functions takes place which may pave the way for decreased resistance to infections.

How are mongoloid children? This question may of course be answered here only fragmentarily As a matter of fact during the first months of life there are often problems no different from those presented by many children They differ from the latter only in that development is retarded in most respects. However their appearance is most often not very strange and they rouse the usual warm feelings in their mothers. It is most often the father who is unable to stand the situation, because he anticipates the sorrows to a much higher degree than the mother his thoughts reach far into a doubtful future while the mother is occupied with the child and her love of it. He is hurt in his pride, or sees his dreams concerning the child—especially when it is a boy—destroyed I feel convinced that often he is the one who should be consoled and supported, if the child's life is to take a harmonious course and this is not quite understood by many doctors. One thinks that it is the unhappy mother who needs support but if one probes under the surface experience shows quite another thing

And how are mongoloid children later on? To start with intelligence the fact is that the majority is mentally moderately deficient (67 %) a certain number severely (20 %) and a certain number slightly deficient (13 %) The highest I Q. I have met with in a 17 year-old mongoloid was 68. But rather more important than this graduation which is based on I Q.s is the fact that the possibilities of mongoloids for development and training in practical fields are considerably greater than those suggested by their I Q.s—if only they are offered the optimal conditions for developing Therefore most often it is not justified to speak of mongoloids and idiocy in the same breath as has been usual and is still done by some persons who are unacquainted with the matter And it is rather absurd to plead generally on the transfer of the mongoloid child to institutions immediately after birth as some doctors do only because these children are unlucky in that the diagnosis can be made as early as that This only expresses a regrettable lack of psychological insight and human understanding and missing knowledge of the facts, since at birth we can say absolutely nothing of the possibilities of the individual for development,

e can only say that the person in question will never be able to shift for himself in community—*but this is true of numerous other people*, and one would never dream of handling them in the same way—even if one could foresee their failure to manage in community. Furthermore we can only seldom predict the reactions of the parents.

It is usual to say that mongoloid children *are affectionate, happy and sensitive* that they have a sense of music and rythm, that they are enterprising, active and meticulous. At any rate, they may develop in this way under favourable conditions. And the few investigations which show that mongoloids do not differ in character or temperament from other mentally deficient individuals with the same level of intelligence originate from observations of patients who have for several years been placed in large institutions, and these investigations may just as well be interpreted to mean that they have not had the optimal conditions to develop their abilities, emotions and character.

Do mongoloid children *hamper* their parents? Yes, if the parents cannot accept the child as it is; if they cannot reduce academical ambitions in favour of affection and love; if they are ashamed and feel that *fate has treated them unfairly*, or if they differ in their opinion about the child. Finally it must be remembered that a mongoloid child may be born into a family already strained in various ways, and to such a family mongoloid child—or even a normal child—may be the last straw that "breaks the camel's back".

Do they hamper their sisters and brothers? Yes, if the parents cannot explain the situation to the other children and provide them with a harmonious existence. However the fear that the mongoloid child as such destroys the lives of sisters and brothers is greatly exaggerated.

Yet I want to emphasize that something special is required in order to make everything glide—qualities, the possession of which cannot be known beforehand.

Which are the optimal conditions for development of mongoloid children? To *this I must answer* quietly and with complete conviction, during the first years of life the child must live at home and must be nursed and cared for like other children in order to get all the stimulation offered at home. We shall have to remember that a home with a mongoloid child often has better possibilities than many others, partly because the members of the family are practically always of normal intelligence and finally because socially and economically they probably belong to a better off group.

But towards school age the problem arises that the child has to get together with other children and has to learn and *even the best home can seldom cope with* these requirements. The primary aim is to make the child capable of helping himself in daily life and to teach him to associate with others in a natural way. Whether the child must now be placed in an institution or not depends on the family environment and on the availability of necessary arrangements in the community such as kindergartens, schools, occupational centres and workshops. Mongoloids can benefit from all these. Many may utilize the kindergarten, some the school, *many the occupational* centres and several the workshop.

Now that we know a great deal of the

optimal conditions for development in mongoloid children, the question is inevitable why are so many mongoloids still often against the intentions of the mental deficiency service sent to large institutions—some of them immediately after birth?

As to the choice—home versus institution—mongoloids differ much from other mentally retarded in that as mentioned before the diagnosis of Down's syndrome can be made early because there are widespread delusions on the possible development of the mongoloids and because there is a widespread superstition that they carry with them misfortunes of all kinds to the home the sisters and brothers The parents attitude has in some cases, to be decided during the very first days of the child's life—especially when the child is born in a clinic. During this period the father and the mother are of course most sensitive and vulnerable and boundlessly much will depend upon communication with a responsible doctor A few words may lead to complete acceptation of the child as it is—or to its complete rejection. I shall not say which mental conflicts rejection may lead to, but I will add that parents who are persuaded to have their child removed and to forget it, have of course a demand for—and will also get, I hope—any support they need from their doctor and other authorities. Sometimes I get the impression that this group of parents has the greatest difficulties; just as we can talk about forgotten children, we can also talk about forgotten parents, and maybe here is an unsolved problem for both the institutions and the parents associations throughout the world.

In spite of all that has been said, mongoloid children will in many cases, be a greater burden to a home than is a normal child. Both psychologic factors and material considerations may under unfavourable conditions rightly tend towards placing a mongoloid child in an institution. In some cases the problems are so closely bound up with and dependent upon the parents personalities that it is the best solution for them—and thus it may be the best for the child too. By the way I believe that there exists an optimal time for placing in an institution those children, who must for some reason or another we cannot predict it with our present knowledge, but it is, at any rate, not in infancy

It is true that mongoloid children develop slowly and that they remain babyish for a long time if only for that reason, there is a great need of nurseries and kindergartens to relieve the mother so that she may perhaps take up her work which keeps her fresh or be free during some of her working hours at home. Direct financial support may also facilitate a difficult situation, and home counselling with advice for play occupation, toilet training eating habits, etc. may do the same All this is inexpensive help compared to costs in an institution, and I guess it will prove to be very effective in the future This is also the case with short stays in an institution in the event of illness in the child's home or in other special situations

All this aims at a trend to keep the mongoloid at home and to help him adapt to the community which is a way out from the former tendency to hide the child in a distant institution.

Certainly mongoloids can never grow

to be independent, but most of them can learn to manage in daily life and heavy scarcity of labour in countries like Holland has proved that mongoloids, too, can meet some of the demands of the assembly belt of existence—and of the Philips-factories, here among other things they are active collaborators in the production of television sets. This gives some idea of the simplicity of the single working process, of course, but it also shows that where there is real need, mongoloids can work on a par with normally gifted individuals. If we want to utilize their capacity for work, however we must take the consequences, offering them the optimal conditions for developing their abilities, as I have outlined them, and not leading them to a side-track from the very beginning.

I have mentioned shortly how and here mongoloids *can* be—not how and where they *must* be and I have mentioned what they *can*—not what they *must* do. I have tried to avoid generalization; but whenever we are confronted with a mongoloid child, we are forced to make a decision which will be of far reaching importance to the individual, his family and the community. In order to be of any help to the parents, the doctor must know much about mongoloids in general and about the individual patient in particular next, he must have an intimate knowledge of the practical support that may be obtained from the community through *external day arrangements o institutions.* And lastly but not leastly he must show in his medical care that the mongoloid child is just as valuable a member of the community and the human race as anybody else.

ere read after 2-3 days. A typical protocol of such determination is shown in Table 1

Schick testing was performed in all mothers and their newborns, using diphtheria toxin of the Sela manufacturing company containing 1/30th of a unit per 0.1 ml. To eliminate possible pseudo-reactions a parallel control injection of heated toxin was always done.

Results and Discussion

Of the 161 mothers only 5, or 3.1%, had a definitely positive Schick test, whereas in another 9 the area of redness was less than 10 × 10 mm, but obviously more pronounced than that of the control injection. This obviously represents an extremely high figure for Schick negative adults since none of these mothers had been actively immunized.

When Zingher made his survey in New York in the early 20s (13) he found that 80 of adults were Schick negative. In 1948 Vahlquist (10, 11) stated that such a figure would not be found anywhere in the Western hemisphere. In an investigation he made in Sweden he found only 0 of adults with a titer of less than 0.02 units of diphtheria antitoxin per ml of serum (9)

In our patients the assay for diphtheria antitoxin showed a good correlation between mother and newborn. When mothers had a measurable antibody titer this was closely reflected in the fetal blood (Table 3)

Von Gröer & Kassowitz (5, 6, 7), studying the antitoxin level in 143 mothers and their newborns, found a closely related titer in 96% of their cases.

The Schick test in all newborns of our 14 positive mothers was unequivocally and uniformly negative (Table 2). This test which, as expected, was positive in mothers with an antibody titer lower than 0.01 units, was shown to be negative in respective newborns (Table 3). This is a difficult point to explain. Why should newborns with low diphtheria antibody titers behave differently on Schick testing than their mothers?

A review of the literature available to us revealed some conflicting data. It is generally accepted that a diphtheria antitoxin concentration of over 1/100 to 1/20 units per ml of blood ensures a negative

Diphtheria Antitoxin Levels and the Schick Reaction in Mothers and their Newborns

by C. PAPADATOS G PAPAEVANGELOU and A KOUKOU

It is well established that infants at birth have circulating antibodies of maternal origin. These antibodies gradually disappear during the first few months of life, and are not usually measurable after 6 months of age As far as we know they represent passive immunity only and their presence in high concentrations during the first few months of life has been shown to be capable of interfering with active immunization.

The antibody pattern in the blood of the newborn depends upon such factors as type of maternal antibody placental permeability degree of fetal maturity and maternal antibody titer Diphtheria antitoxin belongs to a group of antibodies which easily cross the placenta When, therefore mothers have a measurable antibody titer this is obviously closely reflected in the fetal blood.

This paper was designed to study quantitatively the antibody status of the newborn as compared to maternal titers for a single antigen-antibody system namely diphtheria, and to evaluate the Schick test threshhold in mother and newborn in relation to the antibody titer

Materials and Methods

One hundred and sixty one mothers 16–47 years of age and their newborns were Schick tested on the 1st–5th day postpartum. These mothers were of a low socio-economic status and none of them had been actively immunized against diphtheria.

In 18 random cases diphtheria antitoxin was assayed in maternal and cord blood. Serum specimens were obtained aseptically from mothers and their newborns. They were kept at −20°C It is well known that no drop in the titer occurs when serum is kept at −20 for as long as thirty days.

As reference antitoxin we used the standard diphtheria antitoxin, containing 6 units per ml, whereas for diphtheria toxin we used the same toxin employed for the Schick test containing 1/50th of a unit per 0.1 ml.

Antitoxin was titrated by the serum neutralization technique described by Fraser [4] but guinea-pigs instead of rabbits were used By this method varying dilutions of serum were mixed with a known amount of toxin and injected into the skin of the test animal Four determinations were completed on each guinea pig and a parallel titration of the reference antitoxin was always done in the same animal.

As we were mainly interested in the area ranging from 1/30–1/100 units of antitoxin, the following dilutions of sera in saline were done 0 1/5 1/10 1/50 and 1/100. Results

Summary

One hundred and sixty one mothers and their newborns were tested for their Schick state. In [illegible] cases diphtheria antitoxin levels were determined in maternal and cord blood.

A Schick positive reaction was found in 11% of mothers. All newborns were Schick negative.

A good correlation was noted between maternal and cord blood antitoxin levels, as well as between the Schick state and the antitoxin titer in the mother. The discrepancy between antitoxin titer and the Schick reaction in the newborn is discussed.

Schick reaction. This is well documented by our results among tested mothers. Some workers however have reported a Schick negative reaction in persons with less than 0 005 units per ml of blood, as well as Schick positive cases with more than 0 05 units per ml of blood [8]

Wright & Clark [12] have reported a close correlation in the Schick test of mothers and their offspring in 84–85% among 713 tested infants. A discrepancy however has been reported between the results of skin testing in infancy and the presence of antitoxin in the blood, since a proportion of Schick negative infants were found to have little if any circulating antitoxin [8] Schick positive infants with a high antitoxin titer have not been reported up to now in the literature

Our results show that in the newborn there is no correlation between the Schick test and the antitoxin blood level. There are undoubtedly other factors, independent of antitoxin blood titer which determine the skin reaction

Cooke and others have reported similar results with the scarlatinal toxin [1 2 3] They noted that Dick negative newborns become positive at the age of six weeks to three months without change in their blood antitoxin levels.

From our findings we can assume that the Schick negative reaction in the new born infant does not necessarily reflect immunity to diphtheria It is a unique response of the infant s skin toward substances acting against it [9] Since immunologic phenomena in the newborn are so different from those seen in the adult we can not exclude the possibility that this non reactivity against diphtheria toxin is immunologic in nature Moreover since this insensitivity is extended to scarlatinal toxin and maybe to other substances as well more information is necessary to evaluate its nature in the problems of immunity in infancy

Summary

One hundred and sixty one mothers and their newborns were tested for their Schick state. In 18 cases diphtheria antitoxin levels were determined in maternal and cord blood.

A Schick positive reaction was found in 3.1 % of mothers. All newborns were Schick negative.

A good correlation was noted between maternal and cord blood antitoxin levels, as well as between the Schick state and the antitoxin titer in the mother. The discrepancy between antitoxin titer and the Schick reaction in the newborn is discussed.

L'hypercalciurie idiopathique avec nanisme et atteinte rénale chez l'enfant

par PIERRE ROYER

L'hypercalciurie idiopathique sans hypercalcémie a été décrite par Albright en 1953 [1]. Chez l'adulte les circonstances pathologiques à l'occasion desquelles elle a été incriminée sont presque toujours la lithiase urinaire, beaucoup plus rarement l'ostéomalacie et la tétanie.

En 1962, Royer *et coll.* [10, 11] ont isolé chez l'enfant un syndrome caractérisé par une hypercalciurie idiopathique, un nanisme harmonieux, une ostéoporose, un défaut du pouvoir de concentration des urines et parfois une protéinurie de type tubulaire. Simultanément Gentil *et coll.* [5] ont décrit un syndrome identique mais où l'aspect radiologique du squelette était celui d'un rachitisme.

Des observations nouvelles, probablement analogues aux nôtres, ont été rapportées par A. Fanconi [4], Dent *et coll.* [3], Beilin *et coll.* [2], Nordio *et coll.* [9] et Jeune *et coll.* [6]. Ces observations ont démontré: 1° la variabilité du retard de croissance staturale; 2° la possibilité de l'ostéoporose et du rachitisme; 3° l'existence éventuelle de lithiase urinaire ou de néphrocalcinose; 4° l'apparition de ce syndrome quelquefois dès les premiers mois de la vie.

Parmi nos quatre observations primitives [10], l'une a été rejetée comme trop incertaine (obs. IV). Trois autres observations ont pu être analysées depuis. Nous avons vu apparaître dans un cas une néphrocalcinose qui n'existait pas initialement — (obs. II) et dans un cas un rachitisme vitamino-sensible hypocalcémique alors que l'aspect du squelette était primitivement ostéoporotique (obs. V). Dans le dernier cas, hospitalisé en 1966, une néphrocalcinose bilatérale intense s'est installée brusquement entre 9 mois et 18 mois d'âge.

L'étude des observations est résumée en trois parties: symptomatologie, physiologie pathologique, tentatives thérapeutiques.

Symptomatologie

Les circonstances de découverte sont le nanisme, ou une polyurie pitressoré-sistante ou un rachitisme ou des douleurs abdominales ou des crises de tétanie à répétitions dans les premiers mois de la vie.

L'âge où le diagnostic est porté va de 14 à 210 mois. Le sexe est 11 fois masculin et 2 fois féminin. Dans le cas de Beilin

Le père et un frère du malade ont une hypercalciurie. Chez un malade qui nous a été confié par Rossier et Job nous avons aussi trouvé une hypercalciurie chez le père et un frère.

1. *Nanisme*

Le nanisme est important dans presque toutes les observations. Il représente un *écart par rapport à la moyenne de l'âge* de 4 à 5 déviations-standard. Le poids est inférieur ou supérieur à celui correspondant à la taille. La maturation osseuse est toujours en retard par rapport à l'âge chronologique. L'âge osseux correspond souvent à la taille ou lui est un peu supérieur. La maturation dentaire est normale, en rapport avec l'âge chronologique. Le nanisme est harmonieux dans toutes les observations. Ces anomalies sont retrouvées par les autres auteurs, sauf A. Fanconi dont un des malades n'est pas nain.

2. *Anomalies squelettiques*

Outre le retard de l'âge osseux, l'examen radiologique du squelette montre le plus souvent une ostéoporose intense avec un abaissement du rapport cortico-diaphysaire au niveau des os longs et une diminution de la densité du squelette. Dans une observation, un rachitisme y est ajouté en cours d'évolution : il a guéri avec des doses physiologiques de vitamine D.

Toutefois d'autres auteurs ont noté un squelette normal [2] ou un rachitisme [3, 3]. Ce rachitisme est peu sensible ou résistant à la vitamine D.

3. *Anomalies rénales*

Dans tous les cas, il existe une *polyurie*, entre 000 et 500 ml par 24 heures. Dans nos cas, la densité urinaire maximale est entre 1010 et 1020 et la concentration osmolaire maximale est entre 170 et 778 mOsm/kg d'eau. Ce *défaut de concentration* est résistant à la pitressine. Il disparaît ou persiste, suivant les cas, lorsque la calciurie redevient normale.

La *protéinurie* existe dans deux cas sur cinq. Elle se situe entre 0,4 et 3 grammes par jour. Il s'agit d'une protéinurie de type tubulaire avec une globulinurie prédominante.

Les *fonctions rénales* sont satisfaisantes par ailleurs : urée et clearance de la créatinine endogène normales, absence de mélliturie et d'hyperamino-acidurie, pas de syndrome de perte de sel, kaliémie et kaliurie normales; épreuve au chlorure d'ammonium normale dans tous les cas.

Le *coefficient de réabsorption tubulaire* du phosphore est un peu bas et remonte de façon insuffisante lors de la perfusion veineuse de calcium.

Les *biopsies rénales* ont été faites dans cinq observations. Dans deux cas, elles sont normales. Dans trois cas, existe une néphrite interstitielle en foyers.

Les études cytobactériologiques des urines sont toujours normales. L'urographie montre des images non pathologiques. Dans une observation, une néphrocalcinose est apparue en cours d'évolution. Elle existait dès la première année de la vie chez notre dernier malade.

Les mêmes constatations sont faites par d'autres auteurs. Une lithiase avec néphrocalcinose existe dans l'observation 2 de A. Fanconi [4]; une néphrocalcinose nette est retrouvée dans le cas de Bellin [ ] et celui de Jenne [0].

4. *Hypercalciurie*

On peut parler d'hypercalciurie pathologique lorsque la calciurie dépasse 6

mg/kg/24 heures. La *calciurie* moyenne dans nos observations est entre 5 8 et 20 mg/kg/24 heures et la calciurie maximale entre 11 et 38 mg/kg/24 heures. L'hypercalciurie est stable ou variable suivant un rythme saisonnier élevée au printemps et en été plus modérée en période d hiver

La calcémie la phosphatémie les phosphatases alcalines du sérum la citratémie sont normales. Toutefois, dans une observation, la calcémie s est abaissée et une tétanie est survenue. Dans notre dernière observation la première manifestation a été une tétanie à l âge de 3 mois avec hypocalcémie.

Trois faits sont importants 1) la calciurie n augmente pas de façon sensible par des doses quotidiennes de vitamine D voisines de 10 000 unités par jour 2) la calciurie ne s abaisse pas sous l effet de l administration de bicarbonate de sodium contrairement à ce qui se passe dans l acidose tubulaire chronique idiopathique 3) la calciurie diminue par le régime pauvre en calcium le phytate de sodium l hydrochlorothiazide et le régime pauvre en chlorure de sodium

L interprétation de l hypercalciurie prête à deux ordres de discussion. D'une part nous ne l avons retrouvée dans aucune autre variété de nanisme endocrinien, viscéral ostéochondrodystrophique ou essentiel de l enfant D autre part la calciurie exprimée en débit par 24 heures peut etre augmentée dans les diabètes insipides sensibles ou résistants à la pitressine mais jamais au même degré que dans l'hypercalciurie idiopathique En outre la concentration du calcium exprimée par kg de poids et par litre d urine y est diminuée et non augmentée comme dans nos observations

Il convient de compléter cette symptomatologie en précisant que des examens nombreux ont permis d *exclure* 1) tout autre cause de nanisme 2) un syndrome de De Toni–Debré–Fanconi une acidose tubulaire un diabète insipide néphrogénique ou une cystinose 3) une hyperparathyroïdie 4) une sarcoïdose 5) une intoxication par la vitamine D

Physiologie pathologique

La physiologie pathologique de ce syndrome n est pas claire. Il nous paraît probable que l'hypercalciurie est le phénomène central expliquant 1 le trouble de concentration des urines, la protéinurie tubulaire la lithiase et la néphrocalcinose et les lésions éventuelles de néphrite interstitielle en foyer 2° le bilan calcique insuffisamment positif avec en conséquence le nanisme le retard de maturation osseuse et l ostéoporose Toutefois, tout ceci est encore hypothétique

Quant à l *hypercalciurie* elle peut etre liée à un état particulier du calcium plasmatique à une hyperabsorption intestinale à une affection primitive du squelette ou à un processus rénal primitif Les techniques utilisées pour étudier ces faits ont été exposées par ailleurs [12]

1 *État particulier du calcium plasmatique*

Ce fait a été insuffisamment étudié jusqu à présent La citratémie a toujours été normale Le calcium ultrafiltrable a été trouvé normal par Bellin [2] Le calcium ionisé dosé par la méthode de Soulié et Crosnier a été trouvé élevé dans deux de nos observations [12] Des études complémentaires sont nécessaires à ce propos.

— *Affection squelettique primitive*

Une ostéoporose idiopathique pourrait a priori être la cause d'une telle hypercalciurie. Bien que cette épreuve soit discutable, nous avons étudié le « pourcentage de calcium non éliminé dans les urines » au cours de la perfusion calcique. Ce pourcentage de calcium fixé » est entre 65 et 95 pour cent, c'est-à-dire correspond à celui des enfants normaux. Il n'y a pas là d'argument en faveur d'une ostéoporose primitive mais on ne peut pas l'éliminer. La réduction de l'hypercalciurie par le régime pauvre en calcium n'est pas en faveur d'une origine osseuse primitive.

Enfin, l'étude par les radioisotopes, effectuée dans deux de nos observations n'a pas montré d'anomalie de l'accrétion ni de l'ostéolyse.

3. *Hyperabsorption intestinale du calcium*

Des bilans de calcium et de phosphore ont été faits chez nos malades. Le bilan du calcium est entre — 98 et +128 mg/jour c'est-à-dire toujours insuffisamment positif ou négatif. Le pourcentage d'absorption digestive nette du calcium est normal dans trois cas 20, 22 et 23 pour cent et élevé dans deux cas 39 et 60 pour cent. Dans ces conditions, il est difficile d'admettre qu'une absorption intestinale excessive du calcium soit le phénomène primitif dans tous les cas. Les chiffres retrouvés par les autres auteurs sont toutefois sensiblement plus élevés 1, 35, 37 20 et 50 pour cent.

Enfin, la réduction de l'hypercalciurie par le phytate de sodium ou le régime très pauvre en calcium démontre l'influence de l'absorption intestinale sur la calciurie sans qu'il soit possible de conclure à ce certitude.

4. *Origine rénale primitive*

Nous n'avons aucun argument direct en faveur de celle-ci. Toutefois, il est possible que l'action de l'hydrochlorothiazide et celle du régime pauvre en chlorure de sodium s'expliquent ainsi. Nous allons l'envisager à propos de la thérapeutique.

Enfin, *deux constatations* méritent une mention. D'une part la citraturie le plus souvent normale est abaissée dans un de nos cas et dans l'observation de Nordio [9]. L'élimination urinaire des acides du cycle de Krebs, en dehors de l'acide citrique est normale. D'autre part, dans deux de nos observations, les urines ont une forte odeur aromatique. La réaction de Brandt est positive mais les chromatographies sur papier n'ont pas permis d'y retrouver de cystine ou d'acide cystéique en quantité anormale. La chromatographie des dérivés indoliques est normale.

Essais thérapeutiques

Divers essais thérapeutiques ont été faits. En principe, il convient d'abaisser la calciurie pour prévenir la lithiase et la néphrocalcinose et d'améliorer le bilan calcique pour permettre une croissance staturale et osseuse normale et éviter les anomalies de la structure du squelette.

1. La vitamine D. Elle améliore le bilan calcique sans augmenter la calciurie, même à des doses aussi élevées que 10 000 unités par 24 heures. Toutefois, dans une de nos observations, nous avons vu apparaître la néphrocalcinose sur les clichés radiologiques au cours de ce traitement.

— *Le régime pauvre en calcium*, avec un apport quotidien inférieur à 100 mg, diminue la calciurie en général après 5 à

10 jours de ce régime Toutefois, dans ces conditions étudié dans nos trois premières observations le bilan du calcium devient négatif ou très faiblement positif. Ce fait a été retrouvé par A. Fanconi [4] et par Bollin *et coll* [2] Le phytate de sodium a semblé plus intéressant à ces derniers auteurs

3 *L hydrochlorothiazide* à la dose de 5 mg/kg/24 heures abaisse nettement la calciurie D après notre expérience cet effet peut être transitoire Toutefois A. Fanconi a obtenu un effet durable chez un de ces malades [4]

4 Une constatation fortuite nous a montré que *le régime pauvre en chlorure de sodium* diminue la calciurie [13] Dans trois de nos observations, on a mis en évidence une réduction de la calciurie à un taux normal ou presque normal sous l effet d un régime apportant moins de 10 mEq/jour de chlorure de sodium Cet effet est à son maximum lorsqu on dimi nue l apport alimentaire de chlorure de sodium Il est moins net par la seule dimi nution de l apport de sodium Il est plus faible lorsque la diminution porte uni quement sur le chlore Cette diminution de la calciurie s accompagne d une amélio-ration nette du bilan calcique

Cet effet ne peut être secondaire à la seule diminution de la diurèse liée au régime pauvre en sodium puisqu'il s ex prime aussi bien en terme de concentration que de quantité de calcium éliminé dans l urine Il ne peut non plus s expliquer par la seule diminution de la filtration glomé-rulaire Ce fait se rapproche des constata tions faites chez le chien par Walser [14] et chez l'homme normal par Kleeman *et coll.* [8] et par King *et coll* [7]

Les résultats thérapeutiques à long terme du régime pauvre en chlorure de sodium ont pu être étudiés chez deux malades. L un de ces malades a pris, en un an de régime pauvre en chlorure de sodium, 7 cm alors qu au cours des années précédentes il n avait grandi que de 2,5 cm Le second malade à pris 6 5 cm en 10 mois. Ces premiers résultats nous sem blent encourageants pour la poursuite d un tel traitement dans les cas d'hyper calciurie idiopathique de l enfant. Toutefois, récemment, S Balsan a mis en évidence sur ces malades que ce régime entrainait une déplétion en potassium et un arrêt se-condaire de la croissance en taille Il con vient de le compléter par l administration de gluconate de potassium et de l inter rompre un mois par semestre

Resumé

Les observations d un syndrome com portant un nanisme une ostéoporose, un trouble de concentration des urines, une protéinurie de type tubulaire et une hyper calciurie sont analysées.

Le rachitisme la néphrocalcinose et la lithiase urinaire peuvent compléter le tableau Les biopsies rénales montrent une image normale ou une néphrite inter stitielle en foyer

La physiologie pathologique est obscure Deux thérapeutiques peuvent supprimer l hypercalciurie tout en améliorant le bilan calcique l hydrochlorothiazide et surtout le régime pauvre en chlorure de sodium Les premiers résultats de nos régimes pauvres en chlorure de sodium en ce qui concerne en particulier la reprise de la croissance en taille semblent très encou rageants.

no chromosomal abnormalities have been detected.

From the clinical aspect there are three major systems affected, the respiratory tract, the gastrointestinal tract including the pancreas and liver and the eccrine sweat glands. Each system appears to present with different degrees of involvement and with no correlation with the severity of affection. For example the level of sweat electrolytes does not correlate with the degree of pulmonary or pancreatic involvement, nor does the extent of the pulmonary involvement bear any relationship to the pancreas or liver involvement. In addition, the onset of the symptoms varies considerably. In approximately 15% of patients with C.F. the disease process begins in utero, resulting in meconium ileus. In some individuals the symptoms appear in late childhood or early adulthood, as is seen with persistent bronchitis or bronchiectasis with nasal polyposis and sinusitis. The early onset of intestinal and pancreatic insufficiency in patients with meconium ileus is generally accompanied by a later onset of pulmonary disease in most cases [20]. Patients with meconium ileus have the same degree of elevation of sweat electrolytes as those patients in whom the onset of symptoms occurs at a later age. In about 10% to 15% of cases there is no detectable pancreatic enzyme deficiency even as late as 10 years of age. The pancreatic lesion may remain stationary or progress with no reversibility. On the other hand, the secondary pulmonary changes may be reversed to a certain extent by therapeutic measures. The sweat gland function is abnormal from the beginning [21] and remains so throughout life in close to 99% of patients with this disease.

These clinical observations suggest that a search for defects relating to the abnormal electrolytes in sweat or other tissue may provide a factor common to this disease. If such is the case, then we might consider this X factor as being grossly abnormal in the affected child, slightly abnormal or borderline in the heterozygote and normal in healthy individuals. This X factor would be expected to correlate with the severity of disease. Another consideration which leads us away from the pancreas and respiratory tract is the realization that clinical manifestations of those affected organs are secondary effects or complications of the disease process as contrasted to the unknown primary defect.

Although the sweat electrolyte levels provide a satisfactory way for the detection of the homozygous state in cystic fibrosis, this measurement is disappointing as a means of detecting the heterozygote. Di Sant Agnese who was initially impressed with this possibility stated that a significant proportion of relatives (both children and adults) of index cases showed an elevation of sweat electrolytes similar to that found in patients with C.F. [8]. Our earliest report in which the bag test was used was in agreement with Di Sant Agnese [22]. However subsequent studies involving much larger groups of relatives of patients with C.F. and using other methods of sweat stimulation failed to confirm those initial observations [17, 23, 24, 25, 28]. A recent compilation of our sweat test in 73 parents using pilocarpine iontophoresis showed a mean chloride of 33.2 ± 15.5 mEq/l and sodium of 54.9 ± 19.6 mEq/l. An adult control group of 63

Some Genetic Considerations in Cystic Fibrosis A Study of Nail and Sweat Sodium in Two Sibships[1]

by HARRY SHWACHMAN and LOUIS KOPITO

Cystic fibrosis, transmitted as an autosomal recessive trait is one of the most common hereditary diseases in the United States and Western Europe The incidence of cystic fibrosis (C F) in Caucasians has been estimated as ranging from 1 in 400 to 1 in 3700 live births [1 2 3 4 5 6] Our estimate of the incidence of the disease in our community is approximately 1 in 1000 live births. Andersen of New York City [1] estimated an incidence of 1 in 600 in 1946 Accordingly one person in every 16 carries the gene for cystic fibrosis In spite of the relatively widespread prevalence of this gene attempts to detect the heterozygote have been unsuccessful Some authors have stated that parents of children with C F have a significantly elevated sweat sodium and chloride and also have a higher incidence of certain conditions, such as diabetes mellitus, emphysema chronic bronchitis or other forms of chronic pulmonary disease or conditions affecting the intestinal tract such as ulcers and biliary tract disorders [7 8, 9]. The suggestion has also been made that C F plays a significant role in the etiology of chronic bronchitis, peptic ulcer and diabetes mellitus in adults [10 11 12 13]. These reports were critically reviewed by di Sant Agnese & Powell in 1962 [14] leaving this question unresolved We have examined a number of parents of children with C F for the diseases or conditions which were stated to occur with higher frequency in this group Our experience confirmed by Batten *et al.* [15] fails to substantiate these claims We also included pulmonary function tests and sweat tests by the pilocarpine iontophoresis method [16] The findings in sweat are similar to those of other investigators [1 18] and showed no significant differences in the parents and control groups. A recent study [19] in which 132 parents and 118 controls were compared for various acquired diseases particularly of the respiratory and gastrointestinal tract, confirmed the above

At present we are not aware of any metabolic or enzyme defect in cystic fibrosis which would account for the clinical expression of the disease. Mo-

Table 2. Sodium and potassium in finger and toenail clippings from children born to fathers or mothers with C F

Identification	Age	Sodium mEq/Kg	Potassium mEq/kg	Relationship
1. X 822, K. G	3 yrs.	60	24	Daughter of C.F mother
X 822, K. G.	4½ yrs.	43	26	
2. X 780, D K.	6 mos.	113	73	Son of C.F mother
3. X 781, M. R.	12 yrs.	119	84	Son of C.F mother
4. X 640, K. M.		174	170	Son of C.F mother
4. X 670, E. K.		218	84	Son of C.F mother
6. X 1014, J G.	16 yrs.	337	97	Daughter of C F father
7. X 821 J S	9 yrs.	103	83	Son of C.F mother
8. B 111, F F (hair specimen)	17 hrs.	119	4.3	Son of C.F Mother 7 mo. premature, died at 17 hrs.

83, and 98 mEq/l, and very minimal pulmonary symptoms. We cannot make the diagnosis of cystic fibrosis or exclude it with our current information in these three patients. The demonstration of elevated sodium values in nails of the healthy siblings suggested that this analysis may offer clue to the detection of the heterozygote. We accordingly analyzed the nail clippings from 8 known heterozygote infants born to seven mothers and one father with C.F Out of the 8, 7 healthy children showed no evidence of C.F and had elevated nail sodium levels ranging from 108 to 337 mEq/kg (Table 2) In investigating parents of children with C.F (known heterozygotes) we were unable to demonstrate elevated nail sodium concentrations beyond establishing a statistically significant difference in the mean values as compared to those obtained in an adult control group. The range of values obtained in both groups overlapped considerably making it virtually impossible to single out the individual heterozygote for the C.F gene. In searching for an explanation we are studying the effect of age on nail sodium levels. We observed only a small decrease in the level of nail sodium as function of aging

In order to learn more about the nature of the accumulation of sodium in nails and the factors which may produce changes such as diet and environment, we have been observing several families with C F children of different ethnic backgrounds, and residing in widely separated areas. All available immediate relatives of the index case including grandparents, uncles, aunts and first cousins, were given sweat tests and had their nail sodium quantitated periodically Two of those families are selected for illustrative purposes, as seen in Charts 1 and 2 The proband is identified by an arrow The three generation studies are marked I II, and III and denote. (I) grandparents, (II) parents uncles and aunts, and (III) patients, their siblings and cousins. The nail sodium concentration in mEq/kg appears in the left upper corner of the square for males and the circle for females. Sweat sodium levels in mEq/liter are shown in the lower left corner under the nail values. The age, in years at the time of observation, appears outside the square or circle in the upper

TABLE 1 *Distribution of sodium in fingernail and toenail clippings*

	Number	Sodium Mean mEq/Kg	Sodium Range mEq/Kg	Sodium Standard Deviation
1 Patients with C.F	42	232	81–610	104
2. Healthy children under 17 years	63	66	11–700	36
3. Parents of children with C.F	171	74	11–350	40
4. Healthy adults	51	71	11–150	30
Siblings of patients with C.F	184	103	10–320	58

persons had a mean chloride of 29 7 ± 17 7 mEq/l and sodium of 46 8 ± 21.5 mEq/l The small differences between the mean values are not statistically significant.

In view of the elevated sodium in the sweat of patients with cystic fibrosis and the normal or former controversial finding in heterozygotes, we and other investigators have studied sodium in a variety of body fluids and tissues to see if abnormal values would be found The materials studied included serum erythrocytes, urine saliva tears duodenal fluid meconium hair nails, skin and muscles. Except for the markedly elevated sodium in hair and nails, and the reduced value in meconium [20] we found no significant difference which could distinguish individuals with cystic fibrosis on the basis of the sodium concentration in these tissues

Finger and toe nail clippings appeared to store sodium in a manner which provided good differentiation of the patients with C.F [27] A more recent summary which included the total sodium in the nails and nail wash shows that out of 242 patients with C F 231 or about 95 % had nail sodium levels in excess of 110 mEq/Kg of nails. Only 11 patients had values between 80 and 110 mEq/Kg (Table 1) The mean values for the patients with C F was 232 mEq/Kg with a standard deviation of ± 104 In contrast, a group of 63 healthy children under 17 years had a mean nail sodium of 66 ± 30 mEq/Kg We also studied 51 healthy adults, 184 siblings, and 171 parents of the patients and found statistically significant differences between the mean nail sodium levels of all the groups.

On the basis of these observations made over the past three years, we concluded that this test may be a useful diagnostic aid in confirming the clinical impression of the disease It is of definite value in patients showing equivocal sweat sodium levels. When the nail sodium is less than 80 mEq/Kg we can exclude the disease with over 95 % certainty Of special interest are the findings in siblings. The sodium values extend over a large range from normal values seen in healthy subjects to elevated values observed in patients with C F All siblings whose nail clippings were analyzed were seen clinically and subjected to the pilocarpine iontophoresis sweat test. Of the 184 siblings, 181 were healthy and free of respiratory or pancreatic disorders and had normal sweat tests Three had elevated sweat sodium levels, namely 71

TABLE 2.—*Sodium and potassium in finger and toenail clippings from children born to fathers or mothers with C F*

Identification	Age	Sodium mEq/Kg	Potassium mEq/Kg	Relationship

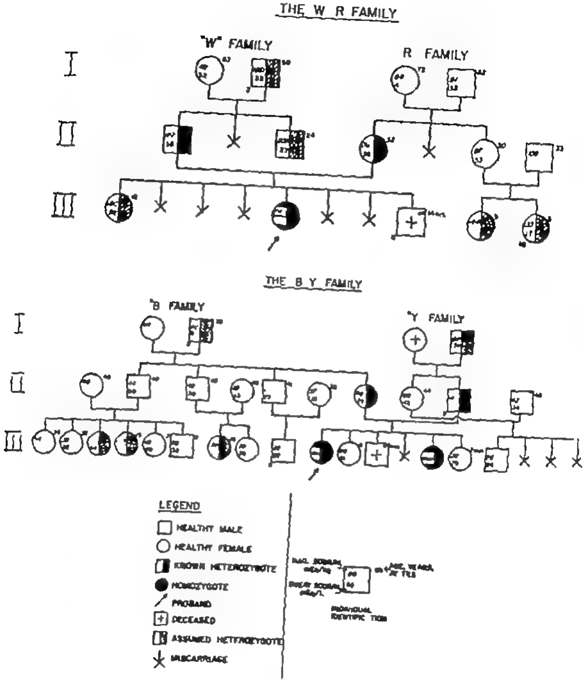
93, and 96 mEq/L and very minimal pulmonary symptoms. We cannot make the diagnosis of cystic fibrosis or exclude it with our current information in these three patients. The demonstration of elevated sodium values in nails of the healthy siblings suggested that this analysis may offer a clue to the detection of the heterozygote. We accordingly analyzed the nail clippings from 8 known heterozygote infants born to seven mothers and one father with C.F Out of the 8 7 healthy children showed no evidence of C.F and had elevated nail sodium levels ranging from 108 to 237 mEq/Kg (Table 2) In investigating parents of children with C.F (known heterozygotes), we were unable to demonstrate elevated nail sodium concentrations beyond establishing statistically significant difference in the mean values as compared to those obtained in an adult control group. The range of values obtained in both groups overlapped considerably making it virtually impossible to single out the individual heterozygote for the C.F gene In searching for an explanation we are studying the effect of age on nail sodium levels. We observed only a small decrease in the level of nail sodium as a function of aging

In order to learn more about the nature of the accumulation of sodium in nails and the factors which may produce changes such as diet and environment, we have been observing several families with C.F children of different ethnic backgrounds, and residing in widely separated areas. All available immediate relatives of the index case, including grandparents, uncles, aunts and first cousins, were given sweat tests and had their nail sodium quantitated periodically Two of these families are selected for illustrative purposes, as seen in Charts 1 and 2. The proband is identified by an arrow The three generation studies are marked I II, and III, and denote (I) grandparents, (II) parents, uncles and aunts, and (III) patients, their siblings and cousins. The nail sodium concentration in mEq/kg appears in the left upper corner of the square for males and the circle for females. Sweat sodium levels in mEq/liter are shown in the lower left corner under the nail values. The age in years at the time of observation, appears outside the square or circle in the upper



right The individual s identification number is shown in the lower left corner An illustrative example appears in the legend The known heterozygotes are the parents of the proband. At least one of the paternal as well as one of the maternal grand parents must be a heterozygote in order to transmit the *C F* gene to the parents of the affected child. *Half* of the children born to these grandparents, i e the parents of the patients and the related uncles and aunts are heterozygotes Accordingly the expected *statistical* frequency of the heterozygote sibling of the patient with

C.F is 2 1 i.e. for every child with C.F two siblings are expected to carry the gene, and one sibling is expected to be normal. The healthy siblings with normal sweat and elevated nail sodium values are assumed to be heterozygotes and are identified graphically as shown in the legend.

The observed values are presented in Charts 1 and 2. A study of the Chart of the W R families shows nail sodium values which demonstrate a theoretically "ideal pattern for the recognition of the heterozygote. The proband, III-5, was diagnosed as having C.F at age one year in 1957 at which time the sweat sodium was 109 mEq/l. The nail analysis done in 1965 showed a sodium concentration of 243 mEq/Kg. The family history revealed that out of 8 pregnancies 5 terminated in miscarriages, and the last infant died at 14 hours. This mother was Rh− and the father Rh+ and during her last pregnancy she developed a high antibody titre. An older sibling, III 1 was subjected to a sweat test when the proband was diagnosed in 1957 and the results showed a sweat sodium of 23 mEq/l. A second sweat test in April 1966 revealed a sodium value of 33 mEq/l, well within the normal range. The nail sodium at this time was markedly elevated, 180 mEq/Kg, and this child was accordingly considered to be an assumed heterozygote Both parents, II 1 and II-4 were sweat tested in 1957 and again in 1966 with normal values. The nail sodium determined in 1966 was markedly elevated and fits the criteria for selecting the heterozygote. In studying the grandparents of the proband we observed normal sweat and nail levels in I 1 and normal sweat with elevated nail sodium in I 2. The grandfather (I *) is, therefore designated as being an "assumed heterozygote The maternal grandparents I-3 and I-4 had normal sweat values but only slightly elevated nail sodium values. The level of these 84 and 91 mEq/kg, fall in the 'borderline zone of 80 to 100 mEq/Kg, between the C.F and normal populations. Values in this range are hard to interpret. Although we know that one of the maternal grandparents must be a heterozygote, the nail sodium levels were not sufficiently elevated to have one of them so designated.

Other observations of interest are those pertaining to the proband s cousins, III 9 and III 10 both of whom have normal sweat levels and slightly elevated nail sodium The values of 144 and 133 mEq/Kg are sufficiently elevated to justify their designation of assumed heterozygotes within the context of this study The proband's uncle II-3, had markedly elevated nail sodium but normal sweat sodium The proband s aunt, II 5 had normal sweat sodium and borderline nail sodium. In this family we observe a generally elevated nail sodium pattern common to all relatives of the proband with the exception of the paternal grandmother I 1

The pedigree of the B.Y family is shown in Chart 2. Only the proband s father II 9 had elevated nail sodium whereas the mother s values were within the range generally seen in a control population. Both children with C.F., III 10 and III 14 have nail sodium levels in the lower 10 % of those common to patients with C.F The grandfather I-4, has both elevated nail and sweat sodium values and gives a history of good health. The maternal grandfather has a nail sodium of 90 mEq/Kg which is in the border line range. Since at least one of the 'B

grandparents is a heterozygote the grand father with the relatively high nail sodium was so designated. Although none of the uncles and aunts had unusually high nail sodium levels three cousins III 3 III-4 and III 7 had elevated nail sodium with normal sweat sodium. If we consider the cousins as being heterozygotes on the basis of the elevated nail sodium their fathers *II 2* and *II 3* should also have had eleva ted nail sodium for they too must be heterozygotes in order to transmit the gene to their children. We are unable to explain these variations from the expec ted patterns of nail sodium in the mother of the patient II 7 and her brothers II 2 and *II-3*

We expect to follow the siblings of the patients with C F which we designated as assumed heterozygotes on the basis of their elevated nail sodium and normal sweat sodium through adulthood and marriage If our assumptions are correct half of their children will have elevated nail sodium and normal sweat values provided their partner does not carry the gene for C F Also as they age their nail sodium levels will diminish until they reach levels which will overlap into a control population range The decline in concen tration of nail sodium with increasing age does not explain the difference noted between parents and healthy adults, thus signifying that this type of assay does not detect the heterozygote in adults In the meantime should a satisfactory meth od be found to detect the heterozygote, its application to these well-studies and cooperative families may be undertaken.

Summary

The rationale for studying tissue that stores sodium as it occurs in nails is presented. The results of our studies on the concentration of sodium in 242 patients with C F., 63 healthy children, 171 parents of children with C F 51 healthy adults and 184 siblings of patients with cystic fibrosis are presented. The elevated nail sodium concentration was detected in over 95 % of the patients with C F and in no patient with C.F was the value less than 80 mEq/kg Seven out of 8 children born to parents, one of whom had C.F showed elevated nail sodium By defini tion these healthy children are the only presently recognized heterozygotes in in fancy The sibling group showed a wide range of values suggesting the possibility of indicating the heterozygote

The nail and sweat sodium results in three generations of two selected sibships is shown in graphic form. Variations are noted which indicate that this type of study does not select the heterozygote for the gene of cystic fibrosis.

The usefulness of the measurement of nail sodium is stated It is hoped that this report will stimulate others to seek other methods for detecting the heterozygote

Familial Leukaemia — Three Cases of Acute Leukaemia in Four Siblings

by K. M. LUNDMARK, ASTRID THILÉN and B. VAHLQUIST

The significance of genetic as compared with environmental factors for the development of leukaemia in man will remain a matter of speculation until our basic concepts have extended considerably further than they have hitherto. By reporting the occurrence of an accumulation of leukaemia cases in the same or successive generations of a single family further perspective on the problem can be achieved. Such reports of familial leukaemia have been recently summarized by Gunz *et al* [7] and Iversen [10] and to their list we now add a family in which three of four siblings died from acute leukaemia.

Case Reports

Notes on the family. This is a family living in a medium-sized factory town in southern Sweden. There is no consanguinity and there have been no other cases of serious blood diseases known among the relatives of the family. The father works in a carton factory and the mother is a housewife. As far as is known, there were no congenital malformations nor exposure to leukaemogenic agents among any of the family members. The pedigree is shown in Figure 1.

The twin brothers, siblings 1 and 2, were regarded as binovular twins since fourfold fetal membranes and double placentas were found at delivery. However they had rather similar physical features and were of the same blood group (O Rh positive). It has not been possible to add further evidence of their zygosity after so many years and interviews with the parents about these problems have been avoided for psychological reasons.

Sibling 1 (born 9/4/47). Pregnancy and delivery were normal. His birth weight was 2.6 kg. He appeared healthy apart from a tendency to mild recurrent upper respiratory infections. In July 1951 considerable enlargement of lymph glands, especially the cervical ones, was noted and after a month when fever supervened, the boy was admitted to the local hospital. Physical examination revealed pallor and enlarged lymph glands, but the liver and spleen were not palpable and there were no signs of bleeding. The laboratory findings were: haemoglobin 9.5 g/100 ml, leucocytes 5,100/mm with 42% lymphocytes and 32 % undifferentiated blast cells, platelets 169 000/mm and sedimentation rate 56 mm/h. A bone marrow aspirate was richly cellular with undifferentiated blast cells as the dominating cell type. The boy was treated with penicillin for two weeks, the fever disappeared and he was sent home. After a further two weeks a pronounced anaemia (haemoglobin 4.5 g/100 ml) and a moderate hepatosplenomegaly were noted and he was given a blood transfusion. A therapeutic trial with urethane (1 g daily) had no noticeable effect and repeated transfusions had to be given. No tendency to

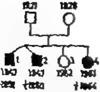

Fig. 1. Pedigree of the family. Year of birth is indicated for all members and year of death for those who died of acute leukaemia (solid symbols).

bleeding was seen. He died 3 months after the initial diagnosis. No autopsy was carried out.

Sibling 2 (born 9/4/47). Pregnancy and delivery were uncomplicated; birth weight was 2.5 kg. He was healthy until mid-January 1950, when he appeared pale and tired. When he was investigated by a physician two weeks later a moderate anaemia (haemoglobin 10.6 g/100 ml) was the only abnormal finding. However the child became febrile and more tired and after a further three weeks he was admitted to hospital. On examination he was pale with moderately enlarged lymph glands, spleen and liver and sparse purpura. The haematological data were haemoglobin 7.7 g/100 ml, leucocytes 18,100/mm³ with 80% undifferentiated blast cells, and sedimentation rate 53 mm/h (platelets not counted). A bone marrow smear was typical of acute leukaemia with marked dominance of undifferentiated blast cells.

The child was sent home after a week on urethane therapy (1 g daily), but no improvement was noted. After five weeks he was again admitted to hospital because of vomiting and pallor. The anaemia was pronounced (haemoglobin 2.0 g/100 ml) and blood transfusion was given. Two weeks later he had sustained high fever and he died at home two months after diagnosis. No autopsy was performed.

Sibling 3 (born 8/51). This girl is now 15 years of age and appears quite healthy.

Sibling 4 (born 10/16/61). Pregnancy and delivery were uneventful. The birth weight was 3.1 kg. She had some minor allergic symptoms, but was otherwise healthy until December 1963 when she became tired. In January 1964 her condition deteriorated with enlargement of the lymph glands and on admission to hospital, hepatosplenomegaly was also noted but no signs of bleeding. Initial blood findings were: haemoglobin 4.9 g/100 ml, leucocytes 148,000/mm with 95% undifferentiated blast cells, platelets 4,000/mm and sedimentation rate 57 mm/h. A bone marrow aspirate revealed a leukaemic picture with almost only undifferentiated blast cells.

The child was given blood transfusion and steroids (triamcinolone 20 mg daily) and improved rapidly with an almost complete remission. Maintenance therapy with steroids was tried, but after two months there was a relapse with a high number of leucocytes, mainly consisting of leukaemic blast cells. A moderate improvement occurred after increased steroid dosage, but one month later both blast cells and anaemia were noted in the peripheral blood. Repeated blood transfusions were given and four months after the initial diagnosis mercaptopurine (37.5 mg daily) was started. A pronounced pancytopenia developed and the mercaptopurine was discontinued.

Five months after diagnosis the patient was admitted to the Paediatric Clinic, Uppsala, for further study. She was extremely cushingoid and a moderate hepatosplenomegaly and minor bleeding signs were noted. There were very few leucocytes and platelets in the peripheral blood but normal haemoglobin (due to recent transfusions). A bone marrow aspirate, however, was hypercellular with numerous leukaemic blast cells, and mercaptopurine and prednisone were given again. Within a few days there was a rise in the numbers of platelets and granulocytes and after two weeks reticulocytosis, and she was sent home. Chromosome analyses of cultured leucocytes showed a normal female karyotype.

The patient underwent a partial remission lasting nearly two months. Thereafter a relapse occurred with pronounced pancytopenia except for high numbers of blast cells. Increased doses of [illegible]

TABLE 1 Clinical data of three siblings with acute leukaemia

Sibling (date of birth)	Sex	Age at diagnosis (years)	Duration of symptoms before diagnosis (weeks)	Type of leukaemia	Therapy	Survival after diagnosis (year)	Comments
1 (9/4/47)	M	3 11/1	4	Acute undifferentiated blast leukaemia	Urethane	3/1	Twins, probably binovular
2 (9/4/47)	M	5/1	3	Acute undifferentiated blast leukaemia	Urethane	*/1*	
4 (10/16/61)	F	3/1	4	Acute undifferentiated blast leukaemia	Corticosteroid mercaptopurine	8/12	Chromosomal study: normal female karyotype

purine had no effect and the patient died eight months after the initial diagnosis. Autopsy revealed marked leukaemic infiltration of the bone marrow and parenchymatous organs and generalized minor bleeding.

Some relevant data concerning the affected children are given in table 1. It appears that all three siblings had many clinical features in common including morphological type. The bone marrow smears from the twin brothers have been reexamined.

Discussion

The idea of a genetic factor as a subsidiary mechanism in the aetiology of leukaemia in man has its origin in observations of the following character.

1. *Epidemiological studies.* The first large study was reported by Videbaek [20]. He found an overrepresentation of leukaemia and malignancies among the relatives of the leukaemia patients (8.1 %) compared to controls (0.5 %). The conclusions drawn from these results have not been free from criticism [10], but the basic observation has been supported by studies of more recent years and thus seems to be valid [21, 13].

2. *Reports of accumulated cases in a single family.* The overall risk of contracting leukaemia is, fortunately, low. In a study on a well-defined Swedish population group the risk of contracting acute leukaemia below the age of 15 years was found to be 0.04 % [3]. The occurrence by mere chance of two cases of acute childhood leukaemia in a sibship should thus be extremely rare. With 3 or more cases specific factors must almost certainly have been operative in the causation of the leukaemia.

In a recent paper by Gunz *et al.* [7] describing 4 (possibly 5) cases of acute leukaemia in a Maori family with 8 children references are made to nine earlier papers on the subject of familial occurrence of the disease (three or more cases). Further observations are probably to be found in the pertinent literature and it is almost

certain that an undefined number of observations will have never been published.

3. *High concordance rates in leukaemia in monovular twins.* An interesting review on this subject has been made by MacMahon & Levy [14] in their analysis of a large series of cases from the United States. They found that when a monovular twin contracts acute leukaemia in childhood, the probability is as high as 25% that the co-twin will develop the disease. In their five sets of monovular twins, both affected, the time interval between the onset of the disease in the first and second twin was from 0 to 10 months (mean 7 months). In each set it was evident that both children had the same type of leukaemia.

However Barber and Speirs [1] and Court Brown & Doll [4] failed to find one single pair of twins, both affected, in their very extensive series from Great Britain.

4. *Higher incidence of acute leukaemia in children with Down's syndrome.* This finding is now well documented, and the risk among children with mongolism has been shown to be about 20 times greater than that of the general population [6].

Miller [16] has recently reviewed the excessive frequency of leukaemia in children with genetically induced diseases.

It is of some interest to determine whether under the circumstances mentioned in points 1–4, leukaemia exhibits any special characteristics.

In unselected series of childhood leukaemia reported by Oehme [18], Hug [9] and Iversen [10] altogether 830 cases, only about 5 % had developed the disease before the age of one year. Among the children with Down's syndrome combined with acute leukaemia, however, in several cases the leukaemia was either present at birth or had its onset during the first year of life [10]. Among the few families with several cases in the same sibship, one is reported [ ] in which 3 out of 5 siblings were shown to have the disease already during the first few months of life.

Familial leukaemia is usually of the same type in the individual cases of the reported families, being generally lymphocytic (lymphoblastic, nondifferentiated blast leukaemia) as also are most cases of childhood leukaemia. However, in congenital leukaemia and the leukaemias in children with Down's syndrome the proportion of the myelocytic type is far larger than in a collected childhood series [10].

In general no correlation has been found between acute leukaemia and congenital malformations other than Down's syndrome [1]. Miller [15] however noted twice as many major congenital defects among leukaemic children as among matched controls, and also an increased incidence of Down's syndrome among siblings of leukaemic children. He suggested that childhood leukaemia was part of a constellation of familial disease.

Chromosomal changes in acute leukaemia are frequently reported but show a great diversity and do not appear to be specific [11]. None of the familial cases with acute leukaemia so far examined have shown any chromosomal abnormality [5]. However, in a familial accumulation of chronic lymphocytic leukaemia an inherited chromosomal abnormality has been reported [8].

In the family described in this report there was no known consanguinity nor

TABLE 1 *Clinical data of three siblings with acute leukaemia*

Sibling (date of birth)	Sex	Age at diagnosis (years)	Duration of symptoms before diagnosis (weeks)	Type of leukaemia	Therapy	Survival after diagnosis (year)	Comments
1 (9/4/47)	M	3 11/12	4	Acute undifferentiated blast leukaemia	Urethane	3/1	Twins, probably binovular
2 (9/4/47)	M	3/1	3	Acute undifferentiated blast leukaemia	Urethane	/1	
4 (10/16/61)	F	3/12	4	Acute undifferentiated blast leukaemia	Corticosteroids mercaptopurine	8/1	Chromosomal study: normal female karyotype

purine had no effect and the patient died eight months after the initial diagnosis. Autopsy revealed marked leukaemic infiltration of the bone marrow and parenchymatous organs and generalized minor bleeding.

Some relevant data concerning the affected children are given in table 1. It appears that all three siblings had many clinical features in common including morphological type. The bone marrow smears from the twin brothers have been reexamined.

Discussion

The idea of a genetic factor as a subsidiary mechanism in the aetiology of leukaemia in man has its origin in observations of the following character.

1. *Epidemiological studies.* The first large study was reported by *Videbaek* [20]. He found an overrepresentation of leukaemia and malignancies among the relatives of the leukaemia patients (8.1 %) compared to controls (0.5 %). The conclusions drawn from these results have not been free from criticism [19], but the basic observation has been supported by studies of more recent years and thus seems to be valid [21, 13].

2. *Reports of accumulated cases in a single family.* The overall risk of contracting leukaemia is, fortunately, low. In a study on a well-defined Swedish population group the risk of contracting acute leukaemia below the age of 15 years was found to be 0.04 % [3]. The occurrence by mere chance of two cases of acute childhood leukaemia in a sibship should thus be extremely rare. With 3 or more cases specific factors must almost certainly have been operative in the causation of the leukaemia.

In a recent paper by *Gunz et al.* [7] describing 4 (possibly 5) cases of acute leukaemia in a Maori family with 8 children, references are made to nine earlier papers on the subject of familial occurrence of the disease (three or more cases). Further observations are probably to be found in the pertinent literature and it is almost

blood dyscrasias. The disease did not differ from ordinary acute lymphoblastic leukaemia with respect to time of onset clinical course or morphological type Two of the siblings were twins, but probably binovular as also were the affected twins in the family described by Gunz *et al.* [7] In our cases the interval between the onset of illness in the first and second twin was 18 months and in the report of Gunz *et al* 21 months

In the pertinent literature considerable interest is paid to the possible influence of noxious factors in the environment [16 17] Such factors may also explain the familial occurrence of a certain disease as an alternative to genetic mechanisms [12] However toxic factors are much more prone to cause aplastic reactions rather than leukaemia In the familial cases irradiation has never been seriously incriminated. We have no reason to suspect any exposure of the members of the reported family to such toxic or irradiating factors.

There is reason to hope that it will not be too long before the aetiology of acute leukaemia in human beings will be seen in a more clear light Even if the hypothesis of viral aetiology gains further support, it will nevertheless be difficult to explain clinical observations of the nature discussed above without the assumption that at least in certain cases, genetic factors must be of some influence.

Summary

An instance of familial leukaemia is described where 3 children out of 4 died of acute lymphocytic leukaemia at the ages of 2–4 years. Two of the siblings were twins probably binovular Genetic mechanisms in the aetiology of acute leukaemia are discussed and the pertinent literature is briefly reviewed.

perform the slightest traumatic procedure such as a venipuncture, was followed by continuous bleeding and by the formation of extensive echymoses at the site of the prick.

In the beginning, we administered prednisone, 2 mg/kg of body weight. This dose was later increased to 4 mg/kg of body weight. At the same time, the patient was transfused with fresh blood and fibrinogen. Nevertheless, in spite of the above treatment, there was no change in either clinical condition or hematological findings. As the patient's condition was deteriorating, we decided to carry out splenectomy. At the time of the operation, the patient had been in hospital for three months. After removal, the spleen was sent for pathological examination and the report was as follows:

Pathology. The spleen was moderately enlarged; it weighed approximately 320 gm and measured 15 × 12 × 3 cm. The medial third of its long axis was occupied throughout its external aspect by a nodular tumour measuring up to 7 cm in greatest diameter. On section, the tumour was hardly discernible. It was of the same consistency and colour as the surrounding splenic tissue. The pulp mass was relatively homogenous, dark red, with indistinct follicles.

Microscopically the tumour showed an angiomatous structure, consisting partly of large sinusoidal spaces packed with red cells, and partly of smaller vascular channels, with a visible lumen. These vascular spaces were lined with flattened endothelium of the splenic pulp; many such lining cells in the angiomatous areas contained free iron pigment.

No lymphoid follicles were present within the nodules. The surrounding splenic tissue was compressed and the follicles immediately adjacent to the tumour were distorted. Some evidence of hemopoiesis was noted in the surrounding tissue.

Post-operative course. Following splenectomy the clinical condition of the patient improved dramatically and the hemorrhagic phenomena disappeared completely. The hematological investigations, immediately after the operation were as follows: The platelet count was 400,000 per cu.mm, the one stage prothrombin time 85%, and the

Giant Hemangioma of the Spleen with Thrombocytopenia and Fibrinogen Deficiency

by N ZERVOS J VLACHOS T KARPATHIOS and J MANTAS

Thrombocytopenic purpura as a complication of a giant hemangioma was first described by Kasabach & Merritt in 1940 [6] Since then nearly sixty similar cases have been published in the world literature In most of these the hemangioma was cutaneous, whereas in only a few the tumour involved the viscera [8]

In this paper we report a case in which a giant hemangioma of the spleen was associated with thrombocytopenia and fibrinogen deficiency

Case Report

X. A a male eight months of age was admitted to the children's hospital "Aglaia Kyriakou" with a 15 days history of purpuric lesions on the face trunk and extremities, epistaxis and hemorrhagic manifestations from the gums. He was born to a 28-year-old female, with a history of one previous normal pregnancy and one miscarriage which occurred during the fourth month of gestation. The pregnancy and delivery were uneventful The birth weight was 3 0 kg There was no history of hemorrhagic disorder in the family The neonatal period was normal and the child did well until the onset of the present illness.

Physical examination on admission He was an unusually pale infant, weighing 9 4 kg His body was covered by extensive purpuric lesions. His blood pressure was 80 mm Hg systolic over 55 mm Hg, diastolic and his pulse rate 110 per min, regular The liver was smooth and palpable 4 cm below the right costal margin, and the spleen, smooth and hard, was palpable 7 cm below the left costal margin

From the other systems: n.a.d.

Laboratory data Hb ranged between 6.3 gm/100 ml and 9.3 gm/100 ml; the leucocyte and differential counts were within normal limits.

The sedimentation rate was 2 mm in one hour The platelet count ranged between 25 000–60,000 per cu.mm. The plasma fibrinogen level was 50 mg/100 ml on three occasions. The one stage prothrombin time was between 15% and 30%. The clot retraction was nil after 4 hours and very little after 24 hours. The bone marrow was normal. The liver function tests were all within normal limits, the blood urea was 38 mg %

Radiological examinations X rays of the skull, chest and long bones were normal, and so was an intravenous pyelogram.

A barium enema showed that the left part of the transverse colon was displaced downwards and to the right; it was pressed by a mass, occupying the left upper side of the abdominal cavity X rays of the abdomen, taken during a barium meal with simultaneous injection of air into the peritoneal cavity showed the stomach to be displaced to the right by a big spleen

Course of Disease The hemorrhagic tendency was so severe that any attempt to

plasma fibrinogen level 200 mg/100 ml. The patient was discharged in excellent condition on the tenth day after splenectomy. The above investigations, repeated two months later, yielded the same results.

Discussion

Because of the location of the hemangioma, this case presented as a difficult diagnostic problem. The diagnosis of idiopathic thrombocytopenic purpura was considered very unlikely in view of the greatly enlarged spleen. Both thrombocytopenia and fibrinogen deficiency appeared to be related to the hemangioma of the spleen, since both subsided after splenectomy.

We were very hesitant about the advisability of splenectomy because of the young age of the patient, the severity of his condition and the fact that his illness was very recent. However, removal of the spleen proved to be literally lifesaving.

This case is interesting because (*a*) hemangiomata rarely develop in the spleen and (*b*) the hemangioma in the spleen was associated not only with thrombocytopenia but also with fibrinogen deficiency. Appropriate investigations to clarify whether other factors in the mechanisms of blood clotting were also deficient were not carried out.

The mechanism by which hemangiomata cause thrombocytopenia is not clear. It was suggested by some authors that it results from decreased platelet production in the bone marrow [10]. Nevertheless, in most of the published cases, including *ours*, the number and the maturation of megacaryocytes in the bone marrow was found to be normal [4]. It is generally accepted that the platelets are destroyed after sequestration within the extensive vascular bed of the hemangioma. This is corroborated by the findings of Kontras *et al.* [7] and Brizel & Raccuglia [3]: following the transfusion of platelets labeled with chromium 51 these authors found increased radioactivity over hemangiomata causing thrombocytopenia. It should be noted, however, that in similar cases Petit [9], Blix & Aas [2] were unable to demonstrate increased radioactivity over the site of the hemangioma.

The associated fibrinogen deficiency in our case, as in other published cases, is difficult to explain. According to Beller & Ruhrmann [1], fibrinogen, together with platelets, is consumed in the process of *hemostasis within the tumour*. Alternatively, fibrinogen deficiency may result from repeated thrombotic episodes occurring in the vascular bed of the tumour; these may set off various fibrinolytic mechanisms [5].

Summary

A case of giant splenic hemangioma associated with thrombocytopenia and fibrinogen deficiency is described. The case presented clinically with severe bleeding and splenomegaly. Treatment with prednisone and transfusions of fresh blood and fibrinogen was unsuccessful in controlling the hemorrhage. Following splenectomy, the patient improved considerably, the bleeding tendency disappeared and the blood findings became normal. The relationship between giant hemangiomata, either visceral or cutaneous, and the disturbed mechanisms of blood clotting is discussed.
